August 18–20, 2010

Outline

1. Radiation Therapy
   - Introduction
   - Radiation therapy delivery
   - Treatment planning
2. Treatment planning
   - Treatment plan evaluation criteria
   - Optimization model
   - Modeling delivery constraints
3. Solution approach
   - Column generation
   - IMRT/VMAT
   - Presenting results
4. Future research

Radiation Therapy

- Each year, about 1.5 million people in the U.S. and 10 million worldwide are newly diagnosed with cancer
  - about 50-65% of these will be treated by some form of radiation therapy
  - about half of these will benefit from *external beam conformal radiation therapy*
- We will discuss optimization problems dealing with the design of *effective* and *efficiently deliverable* radiation therapy treatment plans

Radiation Therapy Delivery

- The most common form of external beam radiation delivery is using a gantry-mounted radiation source generating a rectangular beam of high-energy photons
  - linear accelerator: (megavoltage) X-rays
  - Cobalt source: γ rays

- The radiation source has constant output (intensity)

Radiation Therapy Delivery

- Patients are generally treated
  - with beams from *multiple directions* by rotating the gantry around the patient
  - using non-rectangular (partially blocked) beams
  - daily over a period of 5–8 weeks to allow healthy cells to recover from radiation damage
- Regarding the latter:
  - We will mostly assume that *patient geometry is stationary* and *patients are motionless*
  - We will (briefly) discuss the issue of associated uncertainties later

Radiation Therapy Delivery

- Techniques for partially blocking beams:
  - 3D/Conventional Conformal Radiation Therapy (3DCRT)
    - wedge filters
    - physical apertures (cerrobend)
  - Intensity Modulated Radiation Therapy (IMRT)
    - multileaf collimator (MLC) system
  - Volumetric Modulated Arc Therapy (VMAT)
    - variant of IMRT

3DCRT

- Cerrobend block:

  - In 3DCRT, only a few apertures or filters, typically one from each of a small number of beam orientations, is used

IMRT and VMAT

- A *multi-leaf collimator* (MLC) system consists of leaves that can dynamically block part of a beam to form different *apertures*:

  - In IMRT, several different apertures are formed at each of a relatively small number of beam orientations
  - In VMAT, the gantry rotates continuously while the beam is on and the MLC leaves form apertures

Treatment planning

- We will next focus on two main components:

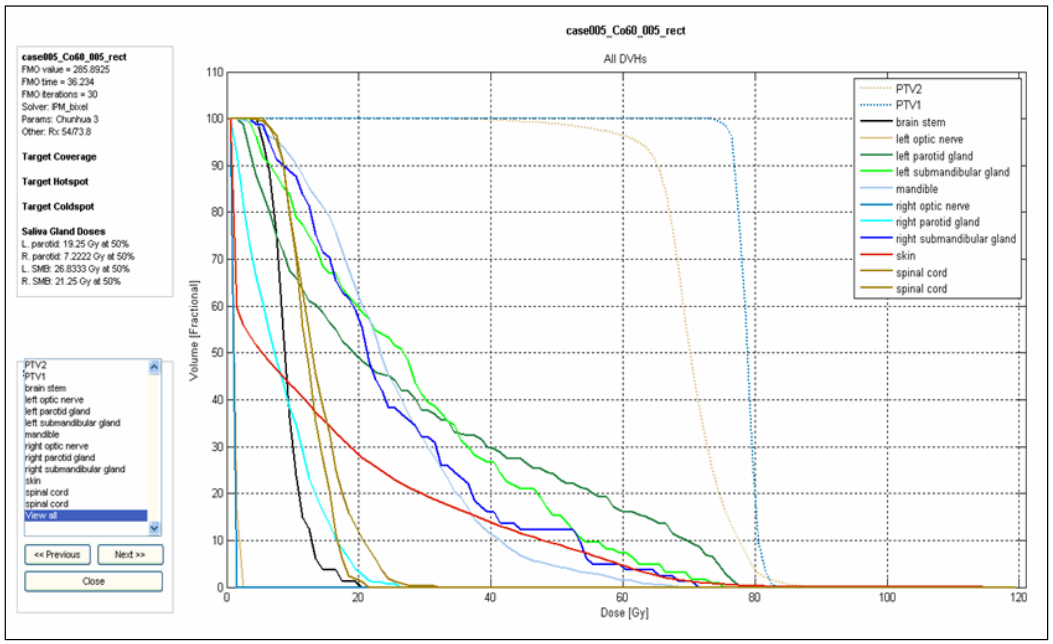
1. *Treatment plan evaluation*
   - Quantifying the quality of a treatment plan (delivered dose distribution)
2. *Treatment plan delivery*
   - Determining a collection of apertures (and/or wedges) with corresponding intensities

Radiotherapy goals

- The goal is to design a treatment plan that
  - delivers a prescribed dose to *targets*
  - while sparing, to the greatest extent possible, *critical structures*
- Radiation therapy therefore seeks to conform the geometric shape of the delivered *dose distribution* to the targets

Evaluation of a dose distribution

- A physician typically considers the dose distribution received by each individual structure
  - The *dose-volume histogram (DVH)* is an important tool that specifies, for each dose value, the fraction of a structure that receives at least that amount of dose



Evaluation of a dose distribution

- Rephrasing the goal of treatment plan design: we wish to identify a treatment plan that has
  - a *desirable* dose distribution in the targets
  - an *acceptable* dose distribution in the critical structures
- Let the random variable D represent the dose (rate) at a uniformly generated point in a structure in the patient
  - Letting F_D denote the cumulative distribution function of D, the DVH of the structure is simply the function $1 - F_D$
- This suggests a connection between (financial) *risk management* and *treatment planning*
  - In both fields, we wish to control the shape of the probability distribution of one or more random variables

[1] Romeijn and Dempsey (TOP, 2008)

Criteria

- Broadly speaking, we wish to penalize
  - overdosing of areas in both target and critical structure
  - underdosing of areas in target
- Physical criteria are therefore often of the form

$$\mathcal{E}\left(u(D)\right)$$

for an appropriately chosen function u

  - In the context of risk management the function u would be a utility function, its shape depending on risk preferences
  - In radiation therapy treatment planning the function u depends on the biological properties of the underlying structure being evaluated

Criteria for underdosing

- *Target*, underdosing
  - u decreasing, usually convex
  - when $u(d) = e^{-\alpha d}$ (with $\alpha > 0$) the expected utility is a monotone transformation of a measure of *tumor control probability* (TCP)

$$\text{TCP} = \exp\left(-N\mathcal{E}\left(e^{-\alpha D}\right)\right)$$

    - $N =$ number of clonogen cells in the target
    - $\alpha =$ rate of cell kill per unit dose

Criteria for overdosing

- *Target or critical structure*, overdosing:
  - u increasing, but shape depends on biological response of tissue to radiation
    - serial: high dose to a small fraction of the structure can destroy its functionality
    - parallel: sparing a part of the structure will preserve its functionality
  - u convex
    - when $u(d) = d^k$ (with $k \geq 1$) the expected utility is a monotone transformation of the so-called *equivalent uniform dose* (EUD)

$$\text{EUD} = \left(E(D^k)\right)^{1/k}$$

  - u "S-shaped"

Criteria

- Other special cases are
  - mean excess or mean shortfall criteria:

$$u(d) = \max\{0, d - T\} \quad \text{or} \quad u(d) = \max\{0, T - d\}$$

    - A related measure is the so-called *Conditional Value-at-Risk*
    - i.e., the upper or lower tail average of the dose distribution

  - *DVH-criteria* that evaluate points on the DVH

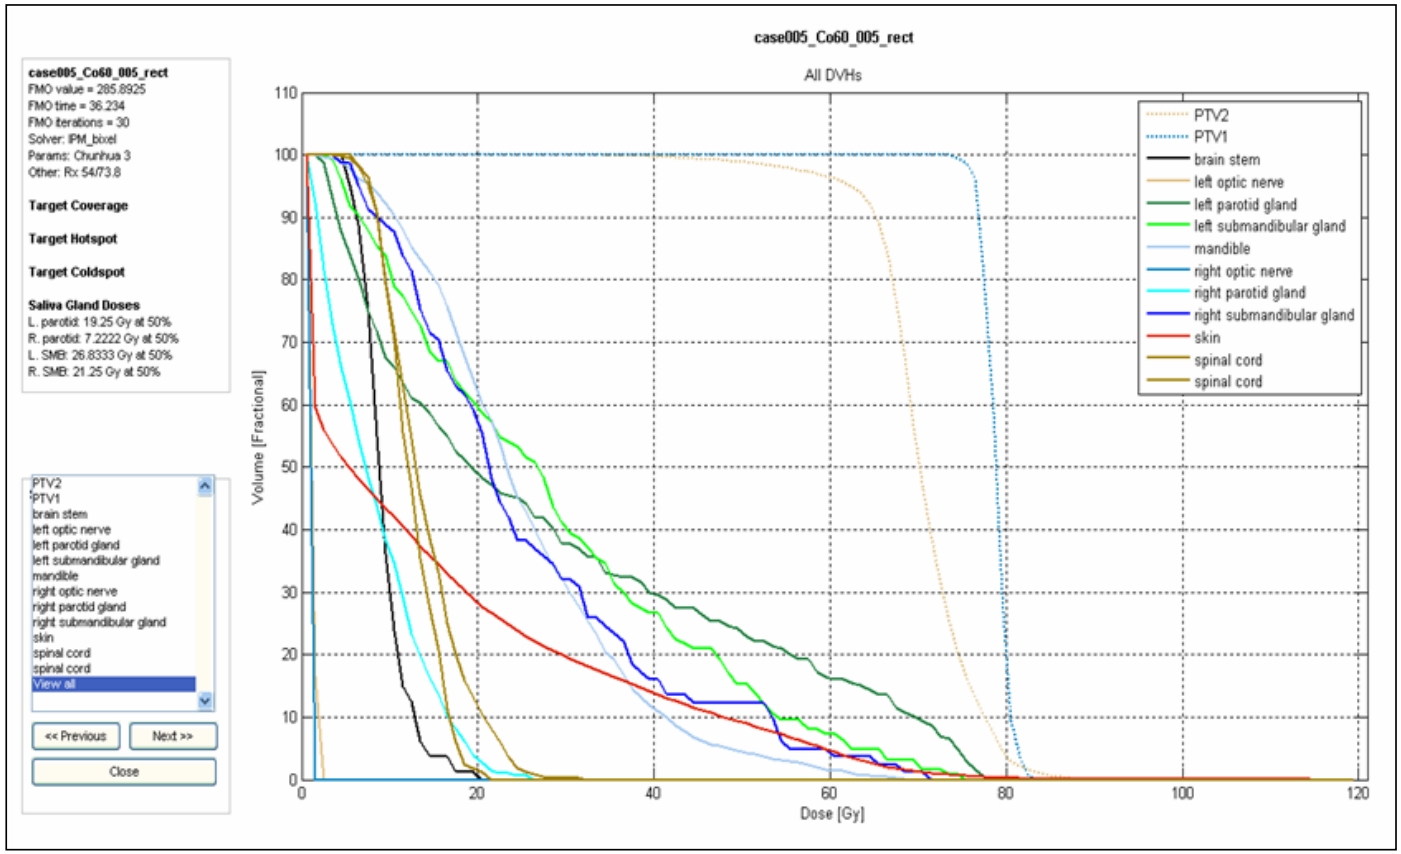
$$u(d) = 1_{[0,T]}(d) \quad \text{or} \quad u(d) = 1_{(T,\infty)}(d)$$

    - A related measure is the so-called *Value-at-Risk*
    - i.e., the dose level that is exceeded by (or not exceeded by) a given fraction of the structure

Criteria

- The latter are often used clinically, and referred to as *DVH criteria*
- Examples:
  - Target:
    - at least 99% of the volume should receive more than 93% of the prescribed dose
    - at least 95% of the volume should receive more than the prescribed dose
  - Saliva gland:
    - at most 50% of the volume should receive more than 30 Gy
    - none of the volume should receive more than 110% of the (target's) prescribed dose

Criteria



case005_Co60_005_rect
FMO value = 285.8925
FMO time = 36.234

Criteria

- More generally, a physician or clinician could specify a full DVH that should dominate the DVH of a structure (from above or below)
  - The bounding DVH corresponds to the c.d.f. of a random variable
  - The dominance constraint is called *first order stochastic dominance*
- A similar dominance could be defined with respect to tail means of the random variable and a bound on the corresponding curve
  - The dominance constraint is then called *second order stochastic dominance*
  - In optimization terms, a second order stochastic dominance constraint is the convex relaxation of a first order stochastic dominance constraint

Objective

- The dose distribution is evaluated over a discretization of the irradiated area into a finite set of cubes (*voxels*), V
- In particular, we consider a collection of treatment plan evaluation criteria:

$$G_\ell(z) : \ell \in L$$

expressed as a function of the dose distribution, i.e., the vector of voxel doses $z \in \mathbb{R}^{|V|}$

  - where smaller values are preferred to larger values

Optimization model

- Optimization model:
  - Objective:
    - single objective, by assigning appropriate weights to the different criteria
    - multi-criteria objective
  - Feasible region:
    - constraints on the value of one or more of the criteria
- An approach that combines these approaches is lexicographic optimization

Beams and apertures

- Let B denote the set of beam orientations used for delivery
  - In IMRT these beam orientations are often (but not necessarily) chosen by the physician or clinician
  - In VMAT we discretize the arc around the patient into a finite number of beam orientations
- The delivery constraints share the concept of an "aperture" (including wedges)
  - Let K_b denote the set of apertures that can be used at beam angle $b \in B$
  - Let $K = \cup_{b \in B} K_b$ be the set of all apertures that can be used for treatment

Data and decision variables

- Dose deposition coefficients:
  - Let $\mathcal{D}_{bkj}$ denote the dose deposited in voxel $j \in V$ from aperture $k \in K_b$ in beam $b \in B$ at unit intensity
- Decision variables:
  - Let y_{bk} denote the intensity of aperture $k \in K_b$, $b \in B$

Model

- Basic optimization model:

$$\text{minimize } G(z) = \sum_{\ell \in L} w_\ell G_\ell(z)$$

subject to

$$z_j = \sum_{b \in B} \sum_{k \in K_b} \mathcal{D}_{bkj} y_{bk} \qquad j \in V$$

$$y_{bk} \geq 0 \qquad k \in K_b,\ b \in B$$

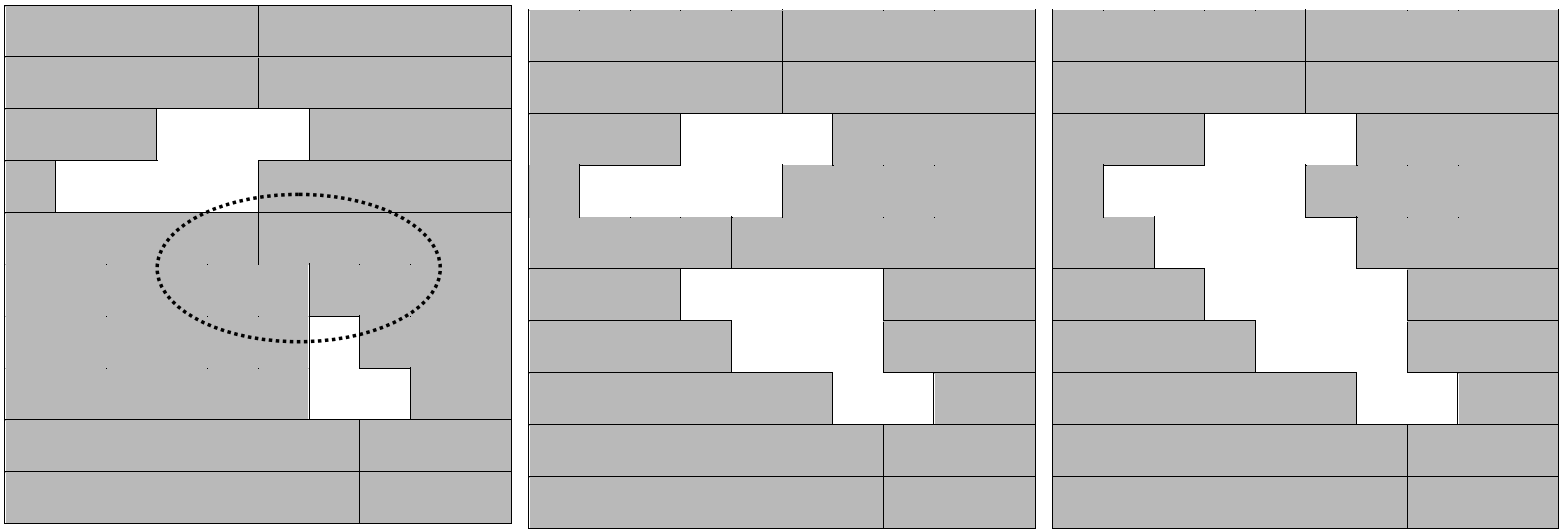
[2] Romeijn, Ahuja, Dempsey, and Kumar (SIAM Journal on Optimization, 2005)

Candidate apertures

- 3DCRT:
  - Usually “beam’s-eye-view” of target from a large number of candidate beam orientations
  - Wedge filters (angle, orientation)
- IMRT/VMAT:
  - Limited by MLC delivery constraints

MLC delivery constraints

- Consecutiveness
- Non-interdigitation
- Connectedness
- Jaws-only



Additional constraints

- VMAT:
  - Leaf motion constraints limit the sequence of apertures
  - Only a single aperture may be used at each beam orientation (at each gantry rotation)
  - It may be possible to vary the gantry speed and/or beam intensity

Additional criteria

- *Beam-on-time*
  - total amount of time the beam is “on”: sum of aperture intensities
- *Total treatment time*:
  - total amount of time the patient is being treated
  - approximated by a weighted sum of beam-on-time and number of apertures used

[3] Salari and Romeijn (in preparation)
[4] Taşkın, Smith, Romeijn, and Dempsey (Operations Research, 2010)
[5] Taşkın, Smith, and Romeijn (Annals of Operations Research, forthcoming)

Additional constraints

- 3DCRT
  - Only a small number of apertures is considered (can be enumerated)
  - Cardinality constraints (on the number of apertures used) are essential
- In the remainder we will focus on
  - IMRT
    - fixed set of beam orientations
    - no (hard) constraint on the number of apertures used
  - VMAT
    - no variation of gantry speed and/or beam intensity

Problem dimension

- The number of available apertures will usually be too large to handle explicitly
- A column generation approach can be used to solve the (continuous relaxation of the) optimization model
  - attractive theoretical properties provided that the objective function G (and any additional constraints) are convex and well-behaved

Pricing problem

- Given an optimal solution to the (relaxed) problem with a limited number of apertures, the pricing problem is of the form:

$$\min_{b \in B} \left(\min_{k \in K_b} \sum_{j \in V} \mathcal{D}_{bkj} \pi_j \right)$$

  where $(\pi_j : j \in V)$ are the KKT multipliers corresponding to the dose definition constraints

- The efficient solvability of this problem depends on
  - The form of the set K_b
  - The dependence of $\mathcal{D}_{bkj}$ on k

Pricing problem

- The pricing problem is efficiently solvable
  - (i) for different models for $\mathcal{D}_{bkj}$
  - (ii) for many practical MLC delivery constraints
- We will illustrate this in the context of IMRT

IMRT

- Example of (i):
  - Discretize each beam orientation into a large grid of "beamlets" (N_b, $b \in B$)
  - Let A_{bk} denote the beamlets that are exposed in aperture $k \in K_b$ in beam $b \in B$
  - Precompute dose deposition coefficients for each beamlet: D_{bij}, $i \in N_b$, $b \in B$
  - Then we can, for example, let

$$\mathcal{D}_{bkj} = \sum_{i \in A_{bk}} D_{bij} + \varepsilon \sum_{i \in N_b \setminus A_{bk}} D_{bij}$$

    - accounts for *transmission* through the MLC leaves
    - other aspects of the MLC leaf architecture can be handled as well

[6] Men, Romeijn, Taşkın, and Dempsey (Physics in Medicine and Biology, 2007)
[7] Salari, Men, and Romeijn (submitted for publication)

IMRT

- Example of (ii):

$$\min_{k \in K_b} \sum_{j \in V} \sum_{i \in A_{bk}} D_{bij} \pi_j = \min_{u \in U_b} \sum_{i \in N_b} \left(\sum_{j \in V} D_{bij} \pi_j \right) u_i$$

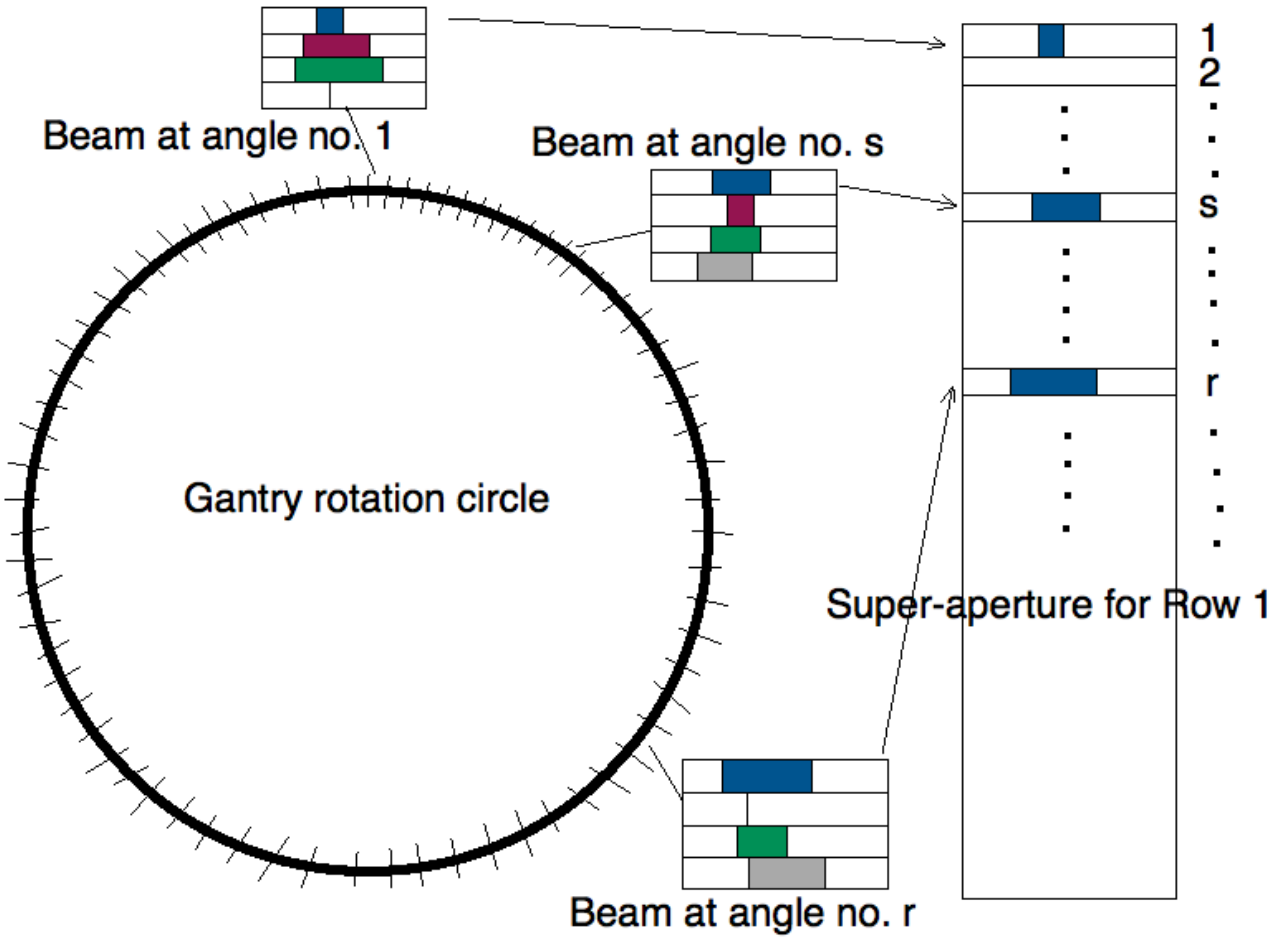
  - Suppose that all row-convex apertures are deliverable
    - Leaf pairs can move independently of one another
    - The pricing problem then decomposes by beamlet row
    - Can be solved in linear time in the number of beamlets in a row

VMAT

- For VMAT we could explicitly add constraints on consecutive apertures to enforce leaf motion constraints
  - tractability of the resulting model is an issue
- However, we can use an approach that resembles the model for IMRT when all row-convex apertures are deliverable
  - Instead of viewing the leaf settings of the entire MLC as an "aperture", we group the leaf settings of a given leaf row as the gantry moves around the patient into an "aperture"
    - one aperture per (discretized) beam angle
    - constraints on the leaf speeds translate into constraints on consecutive pairs of leaf settings in a given row

[8] Peng, Epelman, and Romeijn (in preparation)

VMAT



Beam at angle no. 1
Beam at angle no. s
Gantry rotation circle
Beam at angle no. r
1
2
s
r
Super-aperture for Row 1

Beam vs. beamlet row arc

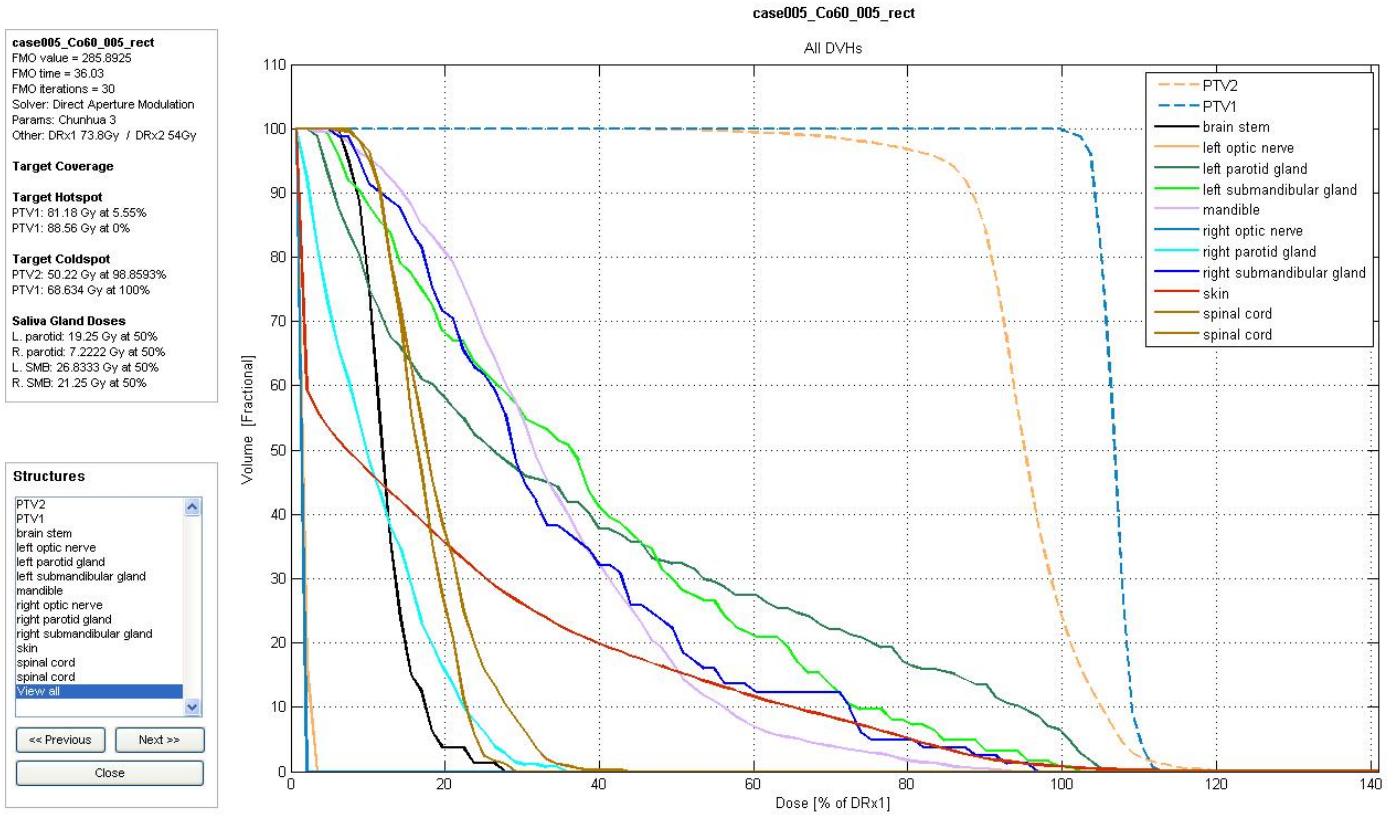
- In the model
  - b now indicates a beamlet row traversing an arc
  - k now indicates a sequence of leaf settings for a given beamlet row traversing an arc
  - The set K_b only contains "apertures" that satisfy the leaf motion constraints
- Pricing problem
  - Solvable in polynomial time using dynamic programming for each beamlet row
    - Stages: beam angles
    - States: pairs of leaf settings at a given beam angle
    - Arcs: connect leaf settings at consecutive angles that are compatible

Results

- Clinical patient cases
- Head-and-neck cancer
  - 2 targets (73.8 Gy and 54 Gy)
  - critical structures: saliva glands (4), spinal cord, brainstem, mandible, . . . (up to 10)

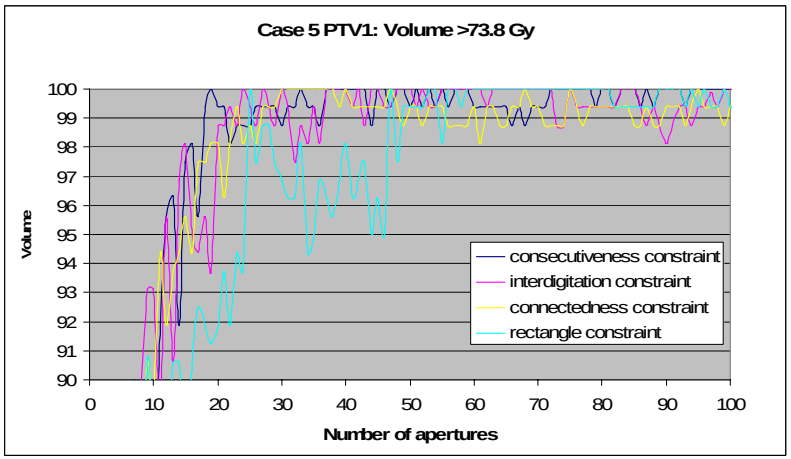
Presentation of results

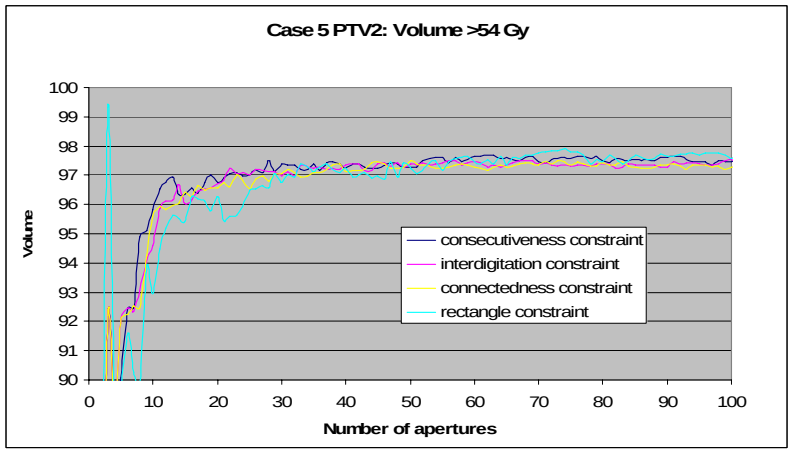
- Traditional: DVHs

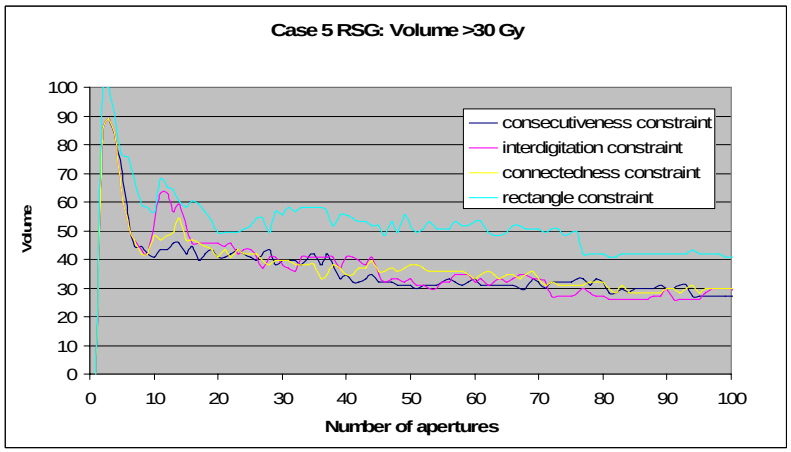


Presentation of results

- Delivery efficiency: clinical criteria vs. number of apertures

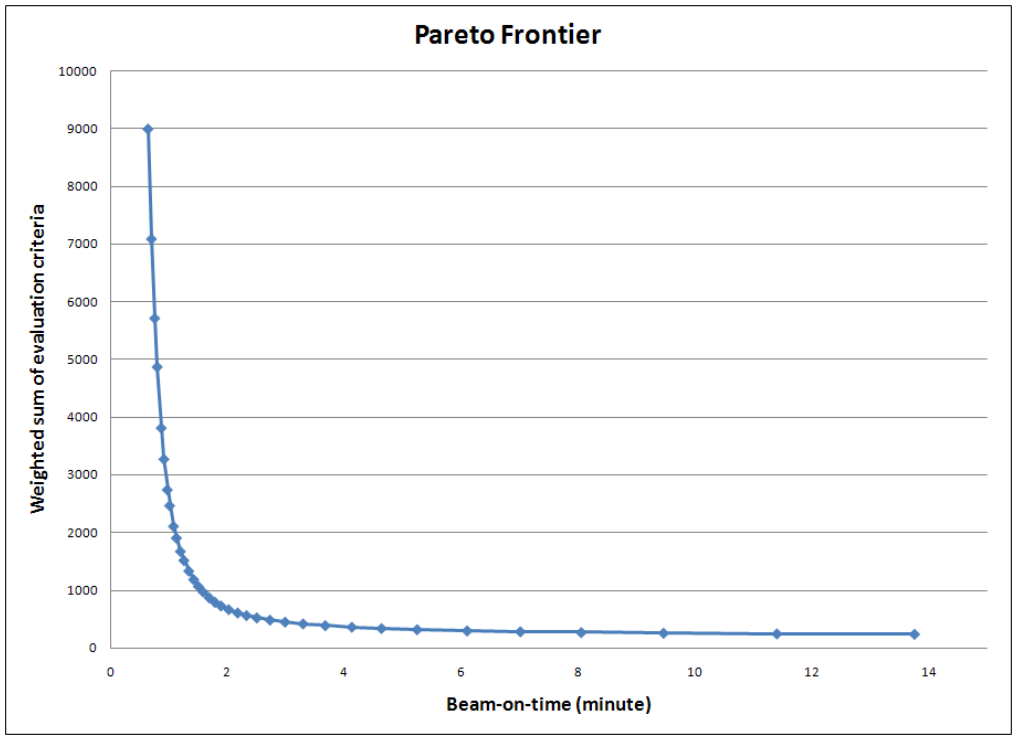






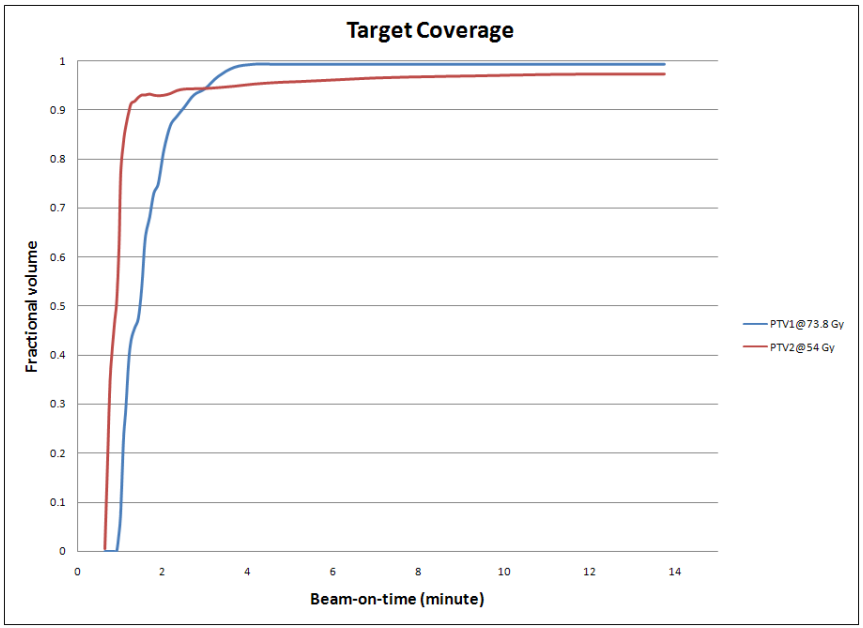
Presentation of results

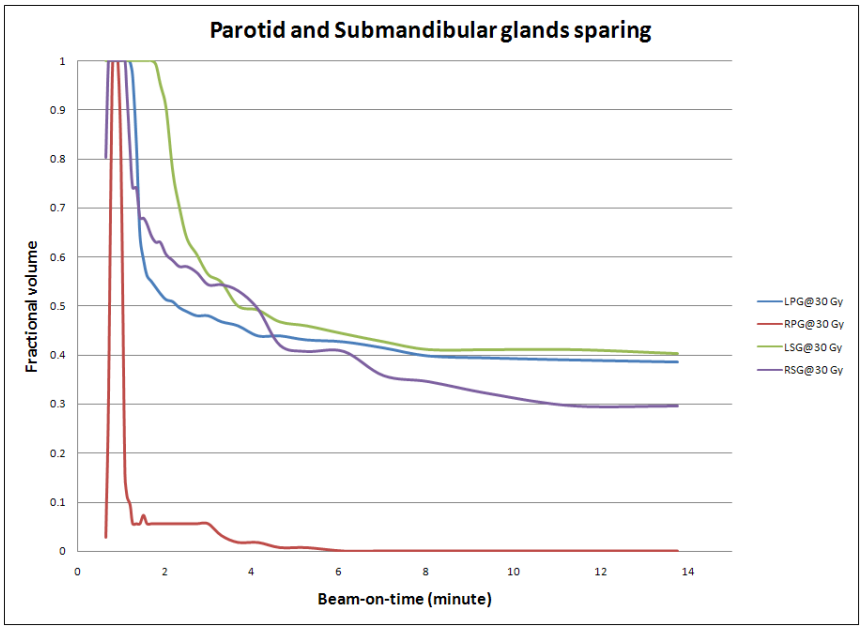
- Delivery efficiency: objective function vs. beam-on-time



Presentation of results

- Delivery efficiency: clinical criteria vs. beam-on-time





Uncertainties (or unknowns)

- Image segmentation (decomposition of V into structures)
  - Manual
  - Automatic
- Dose calculation
  - different models are used to “estimate” the values of D_{bij}, all of them approximate

Uncertainties (or unknowns)

- Treatment plan evaluation (functions G_ℓ)
  - Priorities/weights/tradeoffs
  - Parameter estimation
  - Differences in patient responses

Uncertainties

- Interfraction motion
  - Patient setup (systematic and random)
  - Tumor changes (e.g., shrinkage, growth)
  - Patient geometry changes
    - Structural: e.g., patient weight loss
    - Random: e.g., soft tissues
  - Assessing delivery of nonhomogeneous dose distribution over time
- Intrafraction motion
  - Breathing
  - Swallowing

Margins

- Currently, most of these “uncertainties” are dealt with by using margins to expand structures
- It is tempting to incorporate individual sources of uncertainty into the treatment planning process based on tractability
- It would be valuable to (first) study which of the uncertainties have the most impact on treatment quality

Research directions

- Efficiently exploring tradeoffs
  - between clinical evaluation criteria
  - between quality and efficiency
- Fast reoptimization
  - daily reoptimization based on
    - snapshot image taken before treatment fraction
    - 4D images taken during previous treatment fraction(s)
    - learning about individual patient response
- Intrafraction motion
  - modeling of patient motion
  - monitoring and reacting to patient motion
