Abstract

We present an overview of noncommercial software tools for the solution of mixed-integer linear programs (MILPs). We first review solution methodologies for MILPs and then present an overview of the available software, including detailed descriptions of eight software packages available under open-source or other noncommercial licenses. Each package is categorized as a black-box solver, a callable library, a solver framework, or some combination of these. The distinguishing features of all eight packages are described. The paper concludes with case studies that illustrate the use of two of the solver frameworks to develop custom solvers for specific problem classes and with benchmarking of the six black-box solvers.

1 Introduction

A mixed-integer linear program (MILP) is a mathematical program with linear constraints in which a specified subset of the variables are required to take on integer values. Although MILPs are difficult to solve in general, the past ten years has seen a dramatic increase in the quantity and quality of software—both commercial and noncommercial—designed to solve MILPs. Generally speaking, noncommercial MILP software tools cannot match the speed or robustness of their commercial counterparts, but they can provide a viable alternative for users who cannot afford the sometimes costly commercial offerings. For certain applications,

^{*}jtl13@lehigh.edu

[†]ted@lehigh.edu

open-source software tools can also be more extensible and easier to customize than their commercial counterparts, whose flexibility may be limited by the interface that is exposed to the user. Because of the large number of open-source and noncommercial packages available, it may be difficult for the casual user to determine which of these tools is the best fit for a given task. In this paper, we provide an overview of the features of the available noncommercial and open-source codes, compare selected alternatives, and illustrate the use of various tools. For an excellent overview of the major algorithmic components of commercial solvers, especially CPLEX, LINDO, and XPRESS, we refer to reader to the paper of Atamtürk and Savelsbergh [6].

To formally specify a MILP, let a polyhedron

$$\mathcal{P} = \{x \in \mathbb{R}^n \mid Ax = b, x \geq 0\} \tag{1}$$

be represented in standard form by a constraint matrix $A \in \mathbb{Q}^{m \times n}$ and a right-hand side vector $b \in \mathbb{Q}^m$. Without loss of generality, we assume that the variables indexed 1 through $p \leq n$ are the integer-constrained variables (the *integer variables*), so that the feasible region of the MILP is $\mathcal{P}^I = \mathcal{P} \cap \mathbb{Z}^p \times \mathbb{R}^{n-p}$. In contrast, the variables indexed $p + 1$ through n are called the *continuous variables*. A subset of the integer variables, called *binary variables*, may additionally be constrained to take on only values in the set $\{0, 1\}$. We will denote the set of indices of binary variables by $B \subseteq \{1, 2, \dots, p\}$. The mixed-integer linear programming problem is then to compute the optimal value

$$z_{IP} = \min_{x \in \mathcal{P}^I} c^\top x, \tag{2}$$

where $c \in \mathbb{Q}^n$ is a vector that defines the objective function. The case in which all variables are continuous ($p = 0$) is called a *linear program* (LP). Associated with each MILP is an LP called the *LP relaxation*, obtained by relaxing the integer restrictions on the variables. For the remainder of the paper, we will use this standard notation to refer to the data associated with a given MILP and its LP relaxation.

In what follows, we review the relevant notions from the theory and practice of integer programming and refer to other sources when necessary for the full details of the techniques described. This paper is largely self-contained, though we do assume that the reader is familiar with concepts from the theory of linear programming (see [18]). We also assume that the reader has at least a high-level knowledge of both object-oriented and functional programming interfaces. For an in-depth treatment of the theory of integer programming, we direct the reader to the works of Schrijver [78], Nemhauser and Wolsey [63], and Wolsey [87].

The paper is organized as follows. In Section 2, we sketch the branch-and-cut algorithm, which is the basic method implemented by the solvers we highlight herein, and we describe in some detail the advanced bound improvement techniques employed by these solvers. In

Section 3, we discuss the various categories of MILP software systems and describe how they are typically used. In Section 4, we describe the use and algorithmic features of eight different noncommercial MILP software systems: ABACUS, BCP, BonsaiG, CBC, GLPK, lp_solve, MINTO, and SYMPHONY. Section 5 illustrates the use of two solver frameworks to develop specialized algorithms for solving specific MILP problems. In Section 6, the six noncommercial solvers that can be used as “black-box” solvers are benchmarked on a suite of over 100 MILP instances. We conclude by assessing the current state of the art and trends for the future.

2 Branch and Bound

Branch and bound is a broad class of algorithms that is the basis for virtually all modern software for solving MILPs. Here, we focus specifically on *LP-based branch and bound*, in which LP relaxations of the original problem are solved to obtain bounds on the objective function value of an optimal solution. Roughly speaking, branch and bound is a divide and conquer approach that reduces the original problem to a series of smaller *subproblems* and then recursively solves each subproblem. More formally, recall that \mathcal{P}^I is the set of feasible solutions to a given MILP. Our goal is to determine a least cost member of \mathcal{P}^I (or prove $\mathcal{P}^I = \emptyset$). To do so, we first attempt to find a “good” solution $\bar{x} \in \mathcal{P}^I$ (called the *incumbent*) by a heuristic procedure or otherwise. If we succeed, then $\beta = c^\top \bar{x}$ serves as an initial upper bound on z_{IP} . If no such solution is found, then we set $\beta = \infty$. We initially consider the entire feasible region \mathcal{P}^I . In the *processing* or *bounding* phase, we solve the LP relaxation $\min_{x \in \mathcal{P}} c^\top x$ of the original problem in order to obtain a *fractional solution* $\hat{x} \in \mathbb{R}^n$ and a lower bound $c^\top \hat{x}$ on the optimal value z_{IP} . We assume this LP relaxation is bounded, or else the original MILP is itself unbounded.

After solving the LP relaxation, we consider \hat{x} . If $\hat{x} \in \mathcal{P}^I$, then \hat{x} is an optimal solution to the MILP. Otherwise, we identify k disjoint polyhedral subsets of \mathcal{P} , $\mathcal{P}_1, \dots, \mathcal{P}_k$, such that $\cup_{i=1}^k \mathcal{P}_i \cap \mathbb{Z}^p \times \mathbb{R}^{n-p} = \mathcal{P}^I$. Each of these subsets defines a new MILP with the same objective function as the original, called a *subproblem*. Based on this partitioning of \mathcal{P}^I , we have

$$\min_{x \in \mathcal{P}^I} c^\top x = \min_{i \in 1..k} \left(\min_{x \in \mathcal{P}_i \cap \mathbb{Z}^p \times \mathbb{R}^{n-p}} c^\top x \right), \quad (3)$$

so we have reduced the original MILP to a family of smaller MILPs. The subproblems associated with $\mathcal{P}_1, \dots, \mathcal{P}_k$ are called the *children* of the original MILP, which is itself called the *root subproblem*. Similarly, a MILP is called the *parent* of each of its children. The set of subproblems is commonly associated with a tree, called the *search tree*, in which each node corresponds to a subproblem and is connected to both its children and its parent. We therefore use the term *search tree node* or simply *node* interchangeably with the term

subproblem and refer to the original MILP as the *root node* or *root* of this tree.

After partitioning, we add the children of the root subproblem to the list of *candidate subproblems* (those that await processing) and associate with each candidate a lower bound either inherited from the parent or computed during the partitioning procedure. This process is called *branching*. To continue the algorithm, we select one of the candidate subproblems and process it, i.e., solve the associated LP relaxation to obtain a fractional solution $\hat{x} \in \mathbb{R}^n$, if one exists. Let the feasible region of the subproblem be $\mathcal{S} \subseteq \mathcal{P} \cap \mathbb{Z}^p \times \mathbb{R}^{n-p}$. There are four possible results.

1. If the subproblem has no solutions, then we discard, or *fathom* it.
2. If $c^\top \hat{x} \geq \beta$, then \mathcal{S} cannot contain a solution strictly better than \bar{x} and we may again fathom the subproblem.
3. If $\hat{x} \in \mathcal{S}$ and $c^\top \hat{x} < \beta$, then $\hat{x} \in \mathcal{P}^I$ and is the best solution found so far. We set $\bar{x} \leftarrow \hat{x}$ and $\beta \leftarrow c^\top \bar{x}$, and again fathom the subproblem.
4. If none of the above three conditions hold, we are forced to branch and add the children of this subproblem to the list of candidate subproblems.

We continue selecting subproblems in a prescribed order (called the *search order*) and processing them until the list of candidate subproblems is empty, at which point the current incumbent must be the optimal solution. If no incumbent exists, then $\mathcal{P}^I = \emptyset$.

This procedure can be seen as an iterative scheme for improvement of the difference between the current upper bound, which is the objective function value of the current incumbent, and the current lower bound, which is the minimum of the lower bounds of the candidate subproblems. The difference between these two bounds is called the *optimality gap*. We will see later that there is a tradeoff between improving the upper bound and improving the lower bound during the course of the algorithm.

The above description highlights the four essential elements of a branch-and-bound algorithm:

- *Lower bounding method*: A method for determining a lower bound on the objective function value of an optimal solution to a given subproblem.
- *Upper bounding method*: A method for determining an upper bound on the optimal solution value z_{IP} .
- *Branching method*: A procedure for partitioning a subproblem to obtain two or more children.
- *Search strategy*: A procedure for determining the search order.

With specific implementations of these elements, many different versions of the basic algorithm can be obtained. So far, we have described only the most straightforward implementation. In the sections that follow, we discuss a number of the most common improvements to these basic techniques. Further improvements may be possible through exploitation of the structure of a particular problem class.

2.1 Lower Bounding Methods

The effectiveness of the branch and bound algorithm depends critically on the ability to compute bounds that are close to the optimal solution value. In an LP-based branch-and-bound algorithm, the lower bound is obtained by solving an LP relaxation, as we have indicated. There are a number of ways in which this lower bound can be potentially improved using advanced techniques. In the remainder of this section, we describe those that are implemented in the software packages reviewed in Section 4.

2.1.1 Logical Preprocessing

One method for improving the lower bound that can be applied even before the solution algorithm is invoked is *logical preprocessing*. By application of simple logical rules, preprocessing methods attempt to tighten the initial formulation and thereby improve the bound that produced when the LP relaxation is solved. Formally, preprocessing techniques attempt to determine a polyhedron \mathcal{R} such that $\mathcal{P}^I \subseteq \mathcal{R} \subset \mathcal{P}$. The bound obtained by minimizing over \mathcal{R} is still valid, but may be better than that obtained by minimizing over \mathcal{P} .

Preprocessing techniques are generally limited to incremental improvements of the existing constraint system. Although they are frequently designed to be applied to the original formulation before the solution algorithm is invoked, they can also be applied to individual subproblems during the search process if desired. Preprocessing methods include procedures for identification of obviously infeasible instances, removal of redundant constraints, tightening of bounds on variables by analysis of the constraints, improvement of matrix coefficients, and improvement of the right-hand side value of constraints. For example, a constraint

$$\sum_{j=1}^n a_{ij}x_j \leq b_i$$

can be replaced by the improved constraint

$$\sum_{j \in \{1, \dots, n\} \setminus \{k\}} a_{ij}x_j + (a_k - \delta)x_k \leq b_i - \delta$$

for $k \in B$ such that $\sum_{j \in \{1, \dots, n\} \setminus \{k\}} a_{ij}x_j \leq b_i - \delta \forall x \in \mathcal{P}^I$. This technique is called *coefficient reduction*. Another technique, called *probing*, can be used to determine the

logical implications of constraints involving binary variables. These implications are used in a variety of ways, including the generation of valid inequalities, as described next in Section 2.1.2. An extended discussion of advanced preprocessing and probing techniques, can be found in the paper of Savelsbergh [76].

2.1.2 Valid Inequalities

The preprocessing concept can be extended by dynamically generating entirely new constraints that can be added to the original formulation without excluding members of \mathcal{P}^I . To introduce this concept formally, we define an *inequality* as a pair (a, a_0) consisting of a coefficient vector $a \in \mathbb{R}^n$ and a right-hand side $a_0 \in \mathbb{R}$. Any member of the half-space $\{x \in \mathbb{R}^n \mid a^\top x \leq a_0\}$ is said to *satisfy* the inequality and all other points are said to *violate* it. An inequality is *valid for \mathcal{P}^I* if all members of \mathcal{P}^I satisfy it.

A valid inequality (a, a_0) is called *improving* for a given MILP if

$$\min\{c^\top x \mid x \in \mathcal{P}, a^\top x \leq a_0\} > \min\{c^\top x \mid x \in \mathcal{P}\}.$$

A necessary and sufficient condition for an inequality to be improving is that it is violated by all optimal solutions to the LP relaxation, so violation of the fractional solution $\hat{x} \in \mathbb{R}^n$ generated by solution of the LP relaxation of a MILP is necessary for a valid inequality to be improving. If a given valid inequality violated by \hat{x} is not improving, adding it to the current LP relaxation will still result in the generation of a new fractional solution, however, and may, in turn, result in the generation of additional candidate inequalities. By repeatedly searching for violated valid inequalities and using them to augment the LP relaxation, the bound may be improved significantly. If such an iterative scheme for improving the bound is utilized during the processing of each search tree node, the overall method is called *branch and cut*. Generation of valid inequalities in the root node only is called *cut and branch*. Branch and cut is the method implemented by the vast majority of solvers today.

Valid inequalities that are necessary to the description of $\text{conv}(\mathcal{P}^I)$ are called *facet-defining inequalities*. Because they provide the closest possible approximation of $\text{conv}(\mathcal{P}^I)$, facet-defining inequalities are typically very effective at improving the lower bound. They are, however, difficult to generate in general. For an arbitrary vector $\hat{x} \in \mathbb{R}^n$ and polyhedron $\mathcal{R} \subseteq \mathbb{R}^n$, the problem of either finding a facet-defining inequality (a, a_0) violated by \hat{x} or proving that $\hat{x} \in \mathcal{R}$ is called the *facet identification problem*. The facet identification problem for a given polyhedron is polynomially equivalent to optimizing over the same polyhedron [38], so finding a facet-defining inequality violated by an arbitrary vector is in general as hard as solving the MILP itself. The problem of generating a valid inequality violated by a given fractional solution, whether facet-defining or not, is called the *separation problem*.

To deal with the difficulty of the facet identification problem, a common approach is to generate valid inequalities (possibly facet-defining) for the convex hull of solutions to a relaxation of the instance. In the following paragraphs, we describe commonly arising relaxations of general MILPs and classes of valid inequalities that can be derived from them. In most cases, the relaxations come from substructures that are not present in all MILPs, which means that the associated classes of valid inequalities cannot always be generated. Two exceptions are the Gomory and MIR inequalities, which can be generated for all MILP instances. Most solvers will try to determine automatically which substructures exist and activate the appropriate subroutines for cut generation. However, this is difficult at best. Therefore, if certain substructures are known *not* to exist a priori, then it is worthwhile for the user to disable subroutines that generate the corresponding classes of inequalities. On the other hand, if a particular substructure *is* known to exist, it is worthwhile to seek out a solver that can take advantage of this fact. The classes of valid inequalities covered here are those employed by at least one of the noncommercial solvers that we describe in Section 4.

Although subroutines for generating valid inequalities are generally integrated into the solver itself, free-standing subroutines for generating inequalities valid for generic MILPs can be obtained from the Cut Generation Library (CGL), available for download as part of the Computational Infrastructure for Operations Research (COIN-OR) software suite [19]. The library is provided by the COIN-OR Foundation and includes separation routines for most of the classes of valid inequalities reviewed here. Three of the MILP solvers discussed in Section 4 make use of generic separation routines that are part of the CGL.

Knapsack Cover Inequalities. Often, a MILP has a row i of the form

$$\sum_{j \in B} a_{ij} x_j \leq b_i. \quad (4)$$

We assume without loss of generality that $a_{ij} > 0$ for all $j \in B$ (if not, we can complement the variables for which $a_{ij} < 0$). Considering only (4), we have a relaxation of the MILP, called the 0 – 1 *knapsack problem*, with the feasible region

$$\mathcal{P}^{\text{knapsack}} = \left\{ x \in \{0, 1\}^B \mid \sum_{j \in B} a_j x_j \leq b \right\}.$$

Note that in all of the relaxations we consider, the feasible region is implicitly assumed to be contained in the space $\mathbb{Z}^p \times \mathbb{R}^{n-p}$, and the variables not explicitly present in the relaxation are treated as free. Many researchers have studied the structure of the knapsack problem and have derived classes of facet-defining inequalities for it [7, 43, 85].

A set $C \subseteq B$ is called a *cover* if $\sum_{j \in C} a_j > b$. A cover C is *minimal* if there does not

exist a $k \in C$ such that $C \setminus \{k\}$ is also a cover. For any cover C , we must have

$$\sum_{j \in C} x_j \leq |C| - 1$$

for all $x \in \mathcal{P}^{\text{knapsack}}$. This class of valid inequalities are called *cover inequalities*. In general, these inequalities are not facet-defining for $\mathcal{P}^{\text{knapsack}}$, but they can be strengthened through a procedure called *lifting*. The interested reader is referred to the paper by Gu, Nemhauser, and Savelsbergh [41].

GUB Cover Inequalities. A *generalized upper bound* (GUB) inequality is an inequality of the form

$$\sum_{j \in Q} x_j \leq 1,$$

where $Q \subseteq B$. When MILP contains a knapsack row i of the form (4) and a set of GUB inequalities defined by disjoint sets $Q_k \subset B$ for $k \in K$, we obtain a relaxation of MILP with the feasible region

$$\mathcal{P}^{\text{GUB}} = \left\{ x \in \{0, 1\}^B \mid \sum_{j \in B} a_{ij} x_j \leq b_i, \sum_{j \in Q_k} x_j \leq 1 \quad \forall k \in K \right\}.$$

This class of inequalities models a situation in which a subset of items that does not violate the knapsack inequality (4) must be selected, and within that subset of items, at most one element from each of the subsets Q_i can be selected. A *GUB cover* C_G is a cover that obeys the GUB constraints, (i.e., no two elements of the cover belong to the same Q_i). For any GUB cover C_G , the inequality

$$\sum_{j \in C_G} x_j \leq |C_G| - 1$$

is valid for \mathcal{P}^{GUB} . Again, a lifting procedure, in this case taking into account the GUB constraints, can lead to significant strengthening of these inequalities. For more details of the inequalities and lifting procedure, see the paper of Wolsey [86] and the paper of Gu, Nemhauser, and Savelsbergh [39].

Flow Cover Inequalities. Another important type of inequality commonly found in MILP problems is a *variable upper bound*. A variable upper bound is an inequality of the form

$$x_j \leq U_j x_k,$$

where x_j is a continuous variable ($j > p$), x_k is a binary variable ($k \in B$), and U_j is an upper bound on variable x_j . Such inequalities model the implication $x_k = 0 \Rightarrow x_j = 0$. Variable upper bound inequalities are often used to model a fixed charge associated with

assignment of a positive value to variable x_j , and they are particularly prevalent in network flow models. In such models, we can often identify a relaxation with the following feasible region:

$$\mathcal{P}^{\text{flow}} = \left\{ (x^1, x^2) \in \mathbb{R}_+^{n'} \times \{0, 1\}^{n'} \mid \sum_{j \in N^+} x_j^1 - \sum_{j \in N^-} x_j^1 \leq d, x_j^1 \leq U_j x_j^2, j \in N \right\},$$

where N^+ and N^- are appropriate sets of indices, $N = N^+ \cup N^-$, and $n' = |N|$.

A set $C = C^+ \cup C^-$ is called a *flow cover* if $C^+ \subseteq N^+$, $C^- \subseteq N^-$ and $\sum_{j \in C^+} m_j - \sum_{j \in C^-} m_j > d$. For any flow cover C , the inequality

$$\sum_{j \in C^+} x_j + \sum_{j \in C^{++}} (m_j - \lambda)(1 - y_j) \leq d + \sum_{j \in C^-} m_j + \sum_{j \in L^-} \lambda y_j + \sum_{j \in L^{--}} x_j,$$

where $\lambda = \sum_{j \in C^+} m_j - \sum_{j \in C^-} m_j - d$, $C^{++} = \{j \in C^+ \mid m_j > \lambda\}$, $L^- \subseteq (N^- \setminus C^-)$ and $m_j > \lambda$ for $j \in L^-$, and $L^{--} = N^- \setminus (L^- \cup C^-)$, is called a *simple generalized flow cover inequality* and is valid for $\mathcal{P}^{\text{flow}}$. Just as with knapsack cover inequalities, these inequalities can be strengthened through lifting to obtain an inequality called the *lifted simple generalized flow cover inequality*. The full details of obtaining such inequalities are given by Gu, Nemhauser, and Savelsbergh [40].

Clique Inequalities. Many MILPs contain logical restrictions on pairs of binary variables such as $x_i = 1 \Rightarrow x_j = 0$. In such cases, an auxiliary data structure, called a *conflict graph*, can be used to capture these logical conditions and further exploit them [4]. The conflict graph is a graph with vertex set B , and an edge between each pair of nodes that correspond to a pair of variables that cannot simultaneously have the value one in any optimal solution. The logical restrictions from which the conflict graph is derived may be present explicitly in the original model (for example, GUB inequalities lead directly to edges in the conflict graph), or may be discovered during preprocessing (see [5, 76]).

Because any feasible solution $x \in \mathcal{P}^I$ must induce a vertex packing in the conflict graph, inequalities valid for the vertex packing polytope of the conflict graph are also valid for the MILP instance from which the conflict graph was derived. Classes of inequalities valid for the vertex packing polytope have been studied by a number of authors [17, 44, 64, 66]. As an example, if C is the set of indices of nodes that form a clique in a conflict graph for a MILP instance, then the *clique inequality*

$$\sum_{j \in C} x_j \leq 1$$

is satisfied by all $x \in \mathcal{P}^I$. Alternatively, if O is a cycle in a conflict graph for a MILP

instance, and $|O|$ is odd, then the *odd-hole inequality*

$$\sum_{j \in O} x_j \leq \frac{|O| - 1}{2}$$

is also satisfied by all $x \in \mathcal{P}^I$. Again, these inequalities can be strengthened by lifting [64, 65].

Implication Inequalities. In some cases, the logical implications discovered during pre-processing are not between pairs of binary variables (in which case clique and odd-hole inequalities can be derived), but between a binary variable and a continuous variable. These logical implications can be enforced using inequalities known as *implication inequalities*. If x_i is a binary variable and x_j is a continuous variable with upper bound U_j , the implication

$$x_i = 0 \Rightarrow x_j \leq \alpha$$

yields the implication inequality

$$x_j \leq \alpha + (U_j - \alpha)x_i.$$

Other implication inequalities can also be derived. For more details, see the paper of Savelsbergh [76].

Gomory Inequalities. In contrast to the classes of inequalities we have reviewed so far, Gomory inequalities are generic, in the sense that they do not require the presence of any particular substructure other than integrality and non-negativity. This means they can be derived for any MILP. Gomory inequalities are easy to generate in LP-based branch and bound. After solving the current LP relaxation, we obtain an optimal basis matrix $A_B \in \mathbb{R}^{m \times m}$. The vector $A_B^{-1}b$ yields the values of the basic variables in the current fractional solution \hat{x} . Assuming $\hat{x} \notin \mathcal{P}^I$, we must have $(A_B^{-1}b)_i \notin \mathbb{Z}$ for some i between 1 and m . Taking u above to be the i^{th} row of A_B^{-1} ,

$$x_l + \sum_{j \in NB^I} uA_j x_j + \sum_{k \in NB^C} uA_k x_k = ub, \quad (5)$$

for all $x \in \mathcal{P}^I$, where NB^I is the set of nonbasic integer variables, NB^C is the set of nonbasic continuous variables, and A_l is the l^{th} column of A . Let $f_j = uA_j - \lfloor uA_j \rfloor$ for $j \in NB^I \cup NB^C$, and let $f_0 = ub - \lfloor ub \rfloor$; then the inequality

$$\sum_{\substack{j \in NB^I: \\ f_j \leq f_0}} f_j x_j + \sum_{\substack{j \in NB^I: \\ f_j > f_0}} \frac{f_0(1 - f_j)}{1 - f_0} x_j + \sum_{\substack{j \in NB^C: \\ ua_j > 0}} ua_j x_j - \sum_{\substack{j \in NB^C: \\ ua_j < 0}} \frac{f_0}{1 - f_0} ua_j x_j \geq f_0, \quad (6)$$

is called the *Gomory mixed-integer inequality* and is satisfied by all $x \in \mathcal{P}^I$, but not satisfied by the current fractional solution \hat{x} . It was first derived by Gomory [37], but can also be derived by a simple disjunctive argument, as in Balas *et al.* [8].

Mixed-Integer Rounding Inequalities. Gomory mixed-integer inequalities can be viewed as a special case of a more general class of inequalities known as *mixed-integer rounding inequalities*. Mixed-integer rounding inequalities are obtained as valid inequalities for the relaxed feasible region

$$\mathcal{P}^{\text{MIR}} = \left\{ (x^1, x^2, x^3) \in \mathbb{R}_+^1 \times \mathbb{R}_+^1 \times \mathbb{Z}_+^{n'} \mid \sum_{j=1}^{n'} a_j x_j^3 + x^1 \leq b + x^2 \right\}. \quad (7)$$

The mixed-integer rounding inequality

$$\sum_{j=1}^{n'} \left(\lfloor a_j \rfloor + \frac{\max\{f_j - f, 0\}}{1 - f} \right) x_j^3 \leq \lfloor b \rfloor + \frac{x^2}{1 - f},$$

where $f = b - \lfloor b \rfloor$, $f_j = a_j - \lfloor a_j \rfloor$ for $j = 1, 2, \dots, n'$, is valid for \mathcal{P}^{MIR} [56, 62]. Marchand [55] established that many class of valid inequalities for structured problem instances are special cases of mixed-integer rounding inequalities, including certain subclasses of the lifted flow cover inequalities described above.

The process of generating a mixed-integer rounding inequality is a three-step procedure. First, rows of the constraint matrix are aggregated. Second, bound substitution of the simple or variable upper and lower bounds is performed, and variables are complemented to produce a relaxation of the form (7). Third, a heuristic separation procedure is used to find mixed-integer rounding inequalities valid for some such relaxation and violated by the current fractional solution. Marchand and Wolsey [56] discuss the application of mixed-integer rounding inequalities in detail.

2.1.3 Reduced Cost Tightening

After the LP relaxation of MILP is solved, the reduced costs of nonbasic integer variables can be used to tighten bounds on integer variables for the subtree rooted at that node. Although we have assumed a problem given in standard form, upper and lower bounds on variable values are typically present and are handled implicitly. Such bound constraints take the form $l \leq x \leq u$ for $l, u \in \mathbb{R}^n$ for all $x \in \mathcal{P}^I$. Even if no such bound constraints are initially present, they may be introduced during branching. Let \bar{c}_j be the reduced cost of nonbasic integer variable j , obtained after solution of the LP relaxation of a given subproblem and let $\hat{x} \in \mathbb{R}^n$ be an optimal fractional solution. If $\hat{x}_j = l_j \in \mathbb{Z}$ and $\gamma \in \mathbb{R}_+$ is such that $c^\top \hat{x} + \gamma \bar{c}_j = \beta$, where β is the objective function value of the current incumbent, then $x_j \leq l_j + \lceil \gamma \rceil$ in any optimal solution. Hence, we can replace the previous upper bound u_j with $\min(u_j, l_j + \lceil \gamma \rceil)$. The same procedure can be used to potentially improve the lower bounds. This is an elementary form of preprocessing, but can be very effective when combined with other forms of logical preprocessing, especially when the optimality

gap is small. Note that if this tightening takes place in the root node, it is valid everywhere and can be considered an improvement of the original model. Some MILP solvers store the reduced costs from the root LP relaxation, and use them to perform this preprocessing whenever a new incumbent is found.

2.1.4 Column Generation

A technique for improving the lower bound that can be seen as “dual” to the dynamic generation of valid inequalities is that of *column generation*. Most column generation algorithms can be viewed as a form of Dantzig-Wolfe decomposition, so we concentrate here on that technique. Consider a relaxation of the original MILP with feasible set $\mathcal{F} \supset \mathcal{P}^I$. We assume that \mathcal{F} is finite and that it is possible to effectively optimize over \mathcal{F} , but that a minimal description of the convex hull of \mathcal{F} is of exponential size. Let $\mathcal{Q} = \{x \in \mathbb{R}^n \mid Dx = d, x \geq 0\} \supset \mathcal{P}^I$ be a polyhedron that represents the feasible region of a second relaxation whose description is “small” and such that $\mathcal{F} \cap \mathcal{Q} \cap \mathbb{Z}^p \times \mathbb{R}^{n-p} = \mathcal{P}^I$. We can then reformulate the original integer program as

$$\min \left\{ \sum_{s \in \mathcal{F}} c^\top s \lambda_s \mid \sum_{s \in \mathcal{F}} (Ds) \lambda_s = d, \lambda_s^\top \mathbf{1} = 1, \lambda \geq 0, \lambda \in \mathbb{Z}^{\mathcal{F}} \right\}, \quad (8)$$

where $\mathbf{1}$ is a vector of all ones of conformable dimension. Relaxing the integrality restriction on λ , we obtain a linear program whose optimal solution yields the (possibly) improved bound

$$\min_{x \in \mathcal{F} \cap \mathcal{Q}} c^\top x \geq \min_{x \in \mathcal{P}} c^\top x. \quad (9)$$

Of course, this linear program generally has an exponential number of columns. Therefore, we must generate them dynamically in much the same fashion as valid inequalities are generated in branch and cut. If we solve the above linear program with a subset of the full set of columns to obtain a dual solution u , then the problem of finding the column with the smallest reduced cost among those not already present is equivalent to solving

$$\min_{s \in \mathcal{F}} (c^\top - uD)s, \quad (10)$$

which is referred to as the *column generation subproblem*. Because this is an optimization problem over the set \mathcal{F} , it can be solved effectively, and hence so can the linear program itself. When employed at each search tree node during branch and bound, the overall technique is called *branch and price*.

Because of the often problem-specific nature of the column generation subproblem, branch and price is frequently implemented using a solver framework. Recently two different groups have undertaken efforts to develop generic frameworks for performing column generation. Vanderbeck [84] is developing a framework for branch and price that will take

care of many of the generic algorithmic details and allow the solver to behave essentially as a black box. Galati and Ralphs [70, 35] have undertaken a similar effort in developing DECOMP, a general framework for computing bounds using decomposition within a branch-and-bound procedure. Currently, however, implementing a branch-and-price algorithm is a rather involved procedure that requires a certain degree of technical expertise. Section 5.2 also describes the implementation of a branch-and-price algorithm using the BCP framework.

2.2 Upper Bounding Methods

In branch and bound, upper bounds are obtained by discovering feasible solutions to the original MILP. Feasible solutions arise naturally if the branch-and-bound algorithm is allowed to run its full course. However, acceleration of the process of finding feasible solutions has three potential benefits. First, the solution process may be terminated prematurely and in such a case, we would like to come away with a solution as close to optimal as possible. Second, an improved upper bound β may lead to generation of fewer subproblems because of earlier fathoming (depending on the search strategy being employed). Third, a good upper bound allows the bounds on integer variables to be tightened on the basis of their reduced cost in the current relaxation (see Section 2.1.3). Such tightening can in turn enable additional logical preprocessing and may result in significant improvement to the lower bound as a result.

The process of finding feasible solutions during the search procedure can be accelerated in two ways. The first is to influence the search order, choosing to evaluate and partition nodes that are close to being integer feasible. This technique is further discussed in Section 2.4. The second is to use a heuristic procedure, called a *primal heuristic*, to construct a solution. Primal heuristics are applied during the search process and generally take an infeasible fractional solution as input. A very simple heuristic procedure is to round the fractional components of the infeasible solution in an attempt to produce a feasible solution. The current solution may be rounded in many ways and determination of a rounding that maintains feasibility with respect to the constraints $Ax = b$ may be difficult for certain problem classes. A more sophisticated class of primal heuristics, called *pivot and complement*, involves pivoting fractional variables out of the current linear programming basis in order to achieve integrality [9, 60, 11]. Still other classes of primal heuristics use the solution of auxiliary linear programs to construct a solution. One simple, yet effective example of such a heuristic is known as the *diving* heuristic. In the diving heuristic, some integer variables are fixed and the linear program re-solved. The fixing and re-solving is iterated until either an integral solution is found or the linear program becomes infeasible. Recent successful primal heuristics, such as local branching [29] and RINS [22], combine solution of auxiliary linear programs with methods that control the neighborhood of feasible solutions

to be searched.

2.3 Branching

Branching is the method by which a MILP is divided into subproblems. In LP-based branch and bound, there are three requirements for the branching method. First, the feasible region must be partitioned in such a way that the resulting subproblems are also MILPs. This means that the subproblems are usually created by imposing additional linear inequalities. Second, the union of the feasible regions of the subproblems must contain at least one optimal solution. Third, because the primary goal of branching is to improve the overall lower bound, it is desirable that the current fractional solution not be contained in any of the members of the partition. Otherwise, the overall lower bound will not be improved.

Given a fractional solution to the LP relaxation $\hat{x} \in \mathbb{R}^n$, an obvious way to fulfill the above requirements is to choose an index $j < p$ such that $\hat{x}_j \notin \mathbb{Z}$ and to create two subproblems, one by imposing an upper bound of $\lfloor \hat{x}_j \rfloor$ on variable j and a second by imposing a lower bound of $\lceil \hat{x}_j \rceil$. This partitioning is valid because any feasible solution must satisfy one of these two linear constraints. Furthermore, \hat{x} is not feasible for either of the resulting subproblems. This partitioning procedure is known as *branching on a variable*.

Typically, there are many integer variables with fractional values, so we must have a method for deciding which one to choose. A primary goal of branching is to improve the lower bound of the resulting relaxations. The most straightforward branching methods are those that choose the branching variable based solely on the current fractional solution and do not use any auxiliary information. Branching on the variable with the largest fractional part, the first variable (by index) that is fractional, or the last variable (by index) that is fractional are examples of such procedures. These rules tend to be too myopic to be effective, so many solvers use more sophisticated approaches. Such approaches fall into two general categories: *forward-looking methods* and *backward-looking methods*. Both types of methods try to choose the best partitioning by predicting, for a given candidate partitioning, how much the lower bound will actually be improved. Forward-looking methods generate this prediction based solely on locally generated information obtained by “pre-solving” candidate subproblems. Backward-looking methods take into account the results of previous partitionings to predict the effect of future ones. Of course, as one might expect, hybrids that combine these two basic approaches also exist [2].

A simple forward-looking method is the *penalty method* of Driebeek [26], which implicitly performs one dual simplex pivot to generate a lower bound on the bound improvement that could be obtained by branching on a given variable. Tomlin [81] improved on this idea by considering the integrality of the variables. *Strong branching* is an extension of this basic concept in which the solver explicitly performs a fixed and limited number of dual simplex pivots on the LP relaxations of each of the children that result from branching on

a given variable. This is called *presolving* and again provides a bound on the improvement one might see as a result of a given choice. The effectiveness of strong branching was first demonstrated by Applegate *et al.* in their work on the traveling salesman problem [3] and has since become a mainstay for solving difficult combinatorial problems. An important aspect of strong branching is that presolving a given candidate variable is a relatively expensive operation, so it is typically not possible to presolve all candidates. The procedure is therefore usually accomplished in two phases. In the first phase, a small set of candidates is chosen (usually based on one of the simple methods described earlier). In the second phase, each of these candidates is presolved, and the final choice is made using one of the selection rules to be described below.

Backward-looking methods generally depend on the computation of *pseudocosts* [14] to maintain a history of the effect of branching on a given variable. Such procedures are based on the notion that each variable may be branched on multiple times during the search and the effect will be similar each time. Pseudocosts are defined as follows. With each integer variable j , we associate two quantities, P_j^- and P_j^+ , that estimate the per unit increase in objective function value if we fix variable j to its floor and ceiling, respectively. Suppose that $f_j = \hat{x}_j - \lfloor \hat{x}_j \rfloor > 0$. Then by branching on variable j , we will estimate an increase of $D_j^- = P_j^- f_j$ on the “down branch” and an increase of $D_j^+ = P_j^+(1 - f_j)$ on the “up branch”.

The most important aspect of using pseudocosts is the method of obtaining the values P_j^- and P_j^+ for variable j . A popular way to obtain these values is to simply observe and record the true increase in objective function value whenever variable j is chosen as the branching variable. For example, if a given subproblem had lower bound z_{LP} and its children had lower bounds z_{LP}^- and z_{LP}^+ after branching on variable j , then the pseudocosts would be computed as

$$P_j^- = \frac{z_{LP}^- - z_{LP}}{f_j} \quad P_j^+ = \frac{z_{LP}^+ - z_{LP}}{1 - f_j}, \quad (11)$$

where f_j is the fractional part of the value of variable j in the solution to the LP relaxation of the parent. The pseudocosts may be updated using the first observation, the last observation, or by averaging all observations. In contrast to the estimates generated in strong branching, generation of pseudocost estimates is inexpensive, so they are typically calculated for all variables.

Whether using a forward-looking or a backward-looking method, the final step is to select the branching variable. The goal is to maximize the improvement in the lower bound from the parent to each of its children. Because each parent has two (or more) children, however, no unique metric exists for this change. Suggestions in the literature have included maximization of the sum of the changes on both branches [36], maximization of the smaller of the two changes [12], or a combination of the two [27].

More general methods of branching can be obtained by branching on other disjunctions. For any vector $a \in \mathbb{Z}^n$ whose last $n - p$ entries are zero, we must have $a^\top x \in \mathbb{Z}$ for all $x \in \mathcal{P}^I$. Thus, if $a\hat{x} \notin \mathbb{Z}$, a can be used to produce a disjunction by imposing the constraint $a^\top x \leq \lfloor a^\top \hat{x} \rfloor$ in one subproblem and the constraint $a^\top x \geq \lceil a^\top \hat{x} \rceil$ in the other subproblem. This is known as *branching on a hyperplane*. Typically, branching on hyperplanes is a problem-specific method that exploits special structure, but it can be made generic by maintenance of a pool of inequalities that are slack in the current relaxation as branching candidates.

An example of branching on hyperplanes using special structure is *GUB branching*. If the MILP contains rows of the form

$$\sum_{j \in G} x_j = 1,$$

where $G \subseteq B$, then a valid partitioning is obtained by selection of a nonempty subset G^0 of G , and enforcement of the linear constraint $\sum_{j \in G^0} x_j = 0$ in one subproblem and the constraint $\sum_{j \in G \setminus G^0} x_j = 0$ in the other subproblem. These are linear constraints that partition the set of feasible solutions, and the current LP solution \hat{x} is excluded from both resulting subproblems if G^0 is chosen so that $0 \leq \sum_{j \in G^0} \hat{x}_j < 1$. GUB branching is a special case of branching on *special ordered sets* (SOS)¹ [13]. Special ordered sets of variables can also be used in the minimization of separable piecewise-linear nonconvex functions.

Because of their open nature, noncommercial software packages are often more flexible and extensible than their commercial counterparts. This flexibility is perhaps most evident in the array of advanced branching mechanisms that can be implemented using the open-source and noncommercial frameworks we describe in Section 4. Using a solver framework with advanced customized branching options, it is possible, for instance, to branch directly on a disjunction, rather than introducing auxiliary integer variables. An important example of this is in the handling of semicontinuous variables, in which a variable is constrained to take either the value 0 or a value larger than a parameter K . Additionally, frameworks can make it easy for the user to specify prioritization schemes for branching on integer variables or to implement complex partitioning schemes based on multiple disjunctions.

2.4 Search Strategy

As mentioned in Section 2.3, branching decisions are made with the goal of improving the lower bound. In selecting the order in which the candidate subproblems should be processed, however, our focus may be on improving either the upper bound, the lower bound or both. Search strategies, or *node selection methods*, can be categorized as either *static* methods, *estimate-based* methods, *two-phase* methods, or *hybrid* methods.

¹Some authors refer to GUBs as special ordered sets of type 1

Static node selection methods employ a fixed rule for selecting the next subproblem to process. A popular static method is *best-first search*, which chooses the candidate node with the smallest lower bound. Because of the fathoming rule employed in branch and bound, a best-first search strategy ensures that no subproblem with a lower bound above the optimal solution value can ever be processed. Therefore, the best-first strategy minimizes the number of subproblems processed and improves the lower bound quickly. However, this comes at the price of sacrificing improvements to the upper bound. In fact, the upper bound will only change when an optimal solution is located. At the other extreme, *depth-first search* chooses the next candidate to be a node at maximum depth in the tree. In contrast to best-first search, which will produce no suboptimal solutions, depth-first search tends to produce many suboptimal solutions, typically early in the search process, because such solutions tend to occur deep in the tree. This allows the upper bound to be improved quickly. Depth-first search also has the advantage that the change in the relaxation being solved from subproblem to subproblem is very slight, so the relaxations tend to solve more quickly when compared to best-first search. Some solvers also allow the search tree to be explored in a breadth-first fashion, but this method offers little advantage over best-first search.

Neither best-first search nor depth-first search make any intelligent attempt to select nodes that may lead to improved feasible solutions. Estimate-based methods such as the *best-projection method* [31, 59] and the *best-estimate method* [14] are improvements in this regard. The best-projection method measures the overall “quality” of a node by combining its lower bound with the degree of integer infeasibility of the current solution. Alternatively, the best-estimate method combines a node’s lower bound, integer infeasibility, and pseudocost information to rank the desirability of exploring a node.

Because we have two goals in node selection—finding “good” feasible solutions (i.e., improving the upper bound) and proving that the current incumbent is in fact a “good” solution (i.e., improving the lower bound)—it is natural to develop node selection strategies that switch from one goal to the other during the course of the algorithm. This results in a two-phase search strategy. In the first phase, we try to determine “good” feasible solutions, while in the second phase, we are interested in proving this goodness. Perhaps the simplest “two-phase” algorithm is to perform depth-first search until a feasible solution is found, and then switch to best-first search. A variant of this two-phase algorithm is used by many of the noncommercial solvers that we describe in Section 4.

Hybrid methods also combine two or more node selection methods, but in a different manner. In a typical hybrid method, the search tree is explored in a depth-first manner until the lower bound of the child subproblem being explored rises above a prescribed level in comparison to the overall lower or upper bounds. After this, a new subproblem is

selected by a different criterion (e.g., best-first or best-estimate), and the depth-first process is repeated. For an in-depth discussion of search strategies for mixed-integer programming, see the paper of Linderoth and Savelsbergh [50].

3 User Interfaces

An important aspect of the design of software for solving MILPs is the user interface, which determines both the way in which the user interacts with the solver and the form in which the MILP instance must be specified. The range of purposes for noncommercial MILP software is quite large, so it stands to reason that the number of user interface types is also large. In this section, we broadly categorize the software packages available. The categorization provided here is certainly not perfect—some tools fall between categories or into multiple categories. However, it does represent the most typical ways in which software packages for MILP are employed in practice.

3.1 Black Box Solvers

Many users simply want a “black-box” that takes a given MILP as input and returns a solution as output. For such black-box applications, the user typically interacts with the solver through a command-line interface or an interactive shell, invoking the solver by passing the name of a file containing a description of the instance to be solved. One of the main differences between various black-box solvers from the user’s perspective is the format in which the the model can be specified to the solver. In the two sections below, we describe two of the most common input mechanisms—raw (uninterpreted) file formats and modeling language (interpreted) file formats. Table 1 in Section 4 lists the packages covered in this paper that function as black-box solvers, along with the file formats they accept and modeling languages they support. In Section 6, we provide computational results that compare all of these solvers over a wide range of instances.

3.1.1 Raw File Formats

One of the first interfaces used for black-box solvers was a standard file format for specifying a single instance of a mathematical program. Such a file format provides a structured way of constructing a file containing a description of the constraint matrix and rim vectors (objective function vector, right hand side vector, and variable lower and upper bound vectors) in a form that can be easily read by the solver. The oldest and most pervasive file format is the long-standing Mathematical Programming System (MPS) format, developed by IBM in the 1970s. In MPS format, the file is divided into sections, each of which specifies one of the elements of the input, such as the constraint matrix, the right-hand side, the

objective function, and upper and lower bounds on the variables. MPS is a column-oriented format, which means that the constraint matrix is specified column-by-column in the MPS file. Another popular format, LP format, is similar to MPS in that the format consists of a text file divided into different sections, each of which specifies one of the elements of the input. However, LP format is a row-oriented format, so the constraint matrix is specified one row at a time in the file. This format tends to be slightly more readable by humans.

Because MPS was adopted as the de facto standard several decades ago, there has not been much deviation from this basic approach. MPS, however, is not an extensible standard, and is best suited for specifying integer and linear models. Several replacements based on the extensible markup language (XML), a wide-ranging standard for portable data interchange, have been proposed. One of the most well-developed of these is an open standard called LPFML [32]. The biggest advantage of formats based on XML is that they are far more extensible and are based on an established standard with broad support and well-developed tools.

3.1.2 Modeling Languages

Despite their wide and persistent use, raw file formats for specifying instances have many disadvantages. The files can be tedious to generate, cumbersome to work with, extremely difficult to debug, and are not easily readable by humans. For these reasons, most users prefer to work with a *modeling language*. Modeling languages allow the user to specify a model in a more intuitive (e.g., algebraic) format. An interface layer then interprets the model file and translates it into a raw format that the underlying solver can interpret directly. Another powerful feature of modeling languages is that they allow for the separation of the model specification from the instance data.

Full-featured modeling languages are similar to generic programming languages, such as C and C++, in that they have constructs such as loops and conditional expressions. They also contain features designed specifically to allow the user to specify mathematical models in a more natural, human-readable form. Two modeling language systems that are freely available are ZIMPL [89] and GNU Mathprog (GMPL) [54]. ZIMPL is a stand-alone parser that reads in a file format similar to the popular commercial modeling language AMPL [33] and outputs the specified math program in either MPS or LP format. GMPL is the GNU Math Programming Language, which is again similar to AMPL. The parser for GMPL is included as part of the GLPK package described in Section 4.5, but it can also be used as a free-standing parser.

3.2 Callable Libraries

A more flexible mechanism for invoking a MILP solver is through a callable library interface. Most often, callable libraries are still treated essentially as a “black box,” but they can be invoked directly from user code, allowing the development of custom applications capable of generating a model, invoking the solver directly without user intervention, parsing the output and interpreting the results. Callable libraries also make possible the solution of more than one instance within a single invocation of an application or the use of the solver as a subroutine within a larger implementation. The interfaces to the callable libraries discussed in Section 4 are implemented in either C or C++, with each solver generally having its own Application Programming Interface (API). The column labeled *Callable API* in Table 1 of Section 4 indicates which of the software packages discussed in this paper have callable library interfaces and the type of interface available.

The existence of a different API for each solver makes development of portable code difficult, as this fosters an inherent dependence on one particular API. Recently, however, two open standards for calling solvers have been developed that remove the dependence on a particular solver’s API. These are discussed below.

3.2.1 Open Solver Interface

The Open Solver Interface (OSI), part of the COIN-OR software suite mentioned earlier, is a standard C++ interface for invoking solvers for LPs and MILPs [52]. The OSI consists of a C++ base class with containers for storing instance data, as well as a standard set of problem import, export, modification, solution, and query routines. Each supported solver has a corresponding derived class that implements the methods of the base class and translates the standard calls into native calls to the API of the solver in question. Thus, a code that uses only calls from the OSI base class could be easily interfaced with any supported solver without change. At the time of this writing, eleven commercial and noncommercial solvers with OSI implementations are available, including several of the solvers reviewed in Section 4.

3.2.2 Object-Oriented Interfaces

In an object-oriented interface, there is a mapping between the mathematical modeling objects that comprise a MILP instance (variables, constraints, etc.) and programming language objects. Using this mapping, MILP models can be easily built in a natural way directly within C++ code. The commercial package called Concert Technology [46] from ILOG was perhaps the first example of such an object-oriented interface. FLOPC++ [45] is an open-source C++ object-oriented interface for algebraic modeling of LPs and MILPs that

provides functionality similar to Concert. FLOPC++ allows linear models to be specified in a declarative style, similar to algebraic modeling languages such as GAMS and AMPL, within a C++ program. As a result, the traditional strengths of algebraic modeling languages, such as the ability to declare a model in a human-readable format, are preserved, while still allowing the user is to embed model generation and solution procedures within a larger applications. To achieve solver independence, FLOPC++ uses the OSI to access the underlying solver, and may therefore be linked to any solver with an OSI implementation. Another interesting interface that allows users to model LP instances in the python language is PuLP [75].

3.3 Solver Frameworks

A solver framework is an implementation of a branch-and-bound, branch-and-cut, or branch-and-price algorithm with hooks that allow the user to provide custom implementations of certain aspects of the algorithm. For instance, the user may wish to provide a custom branching rule or problem-specific valid inequalities. The customization is generally accomplished either through the use of C language callback functions, or through a C++ interface in which the user must derive certain base classes and override default implementations for the desired functions. Some frameworks have the ability to function as black-box solvers, but others, such as BCP and ABACUS, do not include default implementations of certain algorithmic components. Table 1 in Section 4 indicates the frameworks available and their style of customization interface.

4 MILP Software

In this section, we summarize the features of the noncommercial software packages available for solving MILPs. Tables 1–3 summarize the packages reviewed here. In Table 1, the columns have the following meanings.

- *Version Number*: The version of the software reviewed for this paper. Note that BCP does not assign version numbers, so we have listed the date obtained instead.
- *LP Solver*: The LP software used to solve the relaxations arising during the algorithm. The MILP solvers listed as OSI-compliant can use any LP solver with an OSI interface. ABACUS can use either CPLEX, SOPLEX, or XPRESS-MP.
- *File Format*: The file formats accepted by packages that include a black-box solver. File formats are discussed in Section 3.1.1.
- *Callable API*: The language in which the callable library interface is implemented (if the package in question has one). Some packages support more than one interface.

Two of the solvers, SYMPHONY and GLPK, can also be called through their own OSI implementation.

- *Framework API*: For those packages that are considered frameworks, this indicates how the callback functions must be implemented—through a C or a C++ interface.
- *User’s Manual*: Indicates whether the package has a user’s manual.

Table 2 indicates the algorithmic features of each solver, including whether the solver has a preprocessor, whether it can dynamically generate valid inequalities, whether it can perform column generation, whether it includes primal heuristics, and what branching and search strategies are available. For the column that indicates available branching methods, the letters stand for the following methods:

- e: pseudocost branching
- f: branching on the variables with the largest fractional part
- h: branching on hyperplanes
- g: GUB branching
- i: branching on first or last fractional variable (by index)
- p: penalty method
- s: strong branching
- x: SOS(2) branching and branching on semi-continuous variables

For the column that indicates available search strategies, the codes stand for the following:

- b: best-first
- d: depth-first
- e: best-estimate
- p: best-projection
- r: breadth-first
- h(x,z): a hybrid method switching from strategy 'x' to strategy 'z'
- 2(x,z): a two-phase method switching from strategy 'x' to strategy 'z'

Finally, Table 3 indicates the classes of valid inequalities generated by those solvers that generate valid inequalities.

In the following sections, we provide an overview of each solver, then describe the user interface, and finally describe the features of the underlying algorithm in terms of the four categories listed in Section 2. In what follows, the reader should keep in mind that solver performance can vary significantly with different parameters settings, and it

	Version Number	LP Solver	File Format	Callable API	Framework API	User's Manual
ABACUS	2.3	C/S/X	no	none	C++	yes
BCP	11/1/04	OSI	no	none	C++	yes
bonsaiG	2.8	DYLP	MPS	none	none	yes
CBC	0.70	OSI	MPS	C++/C	C++	no
GLPK	4.2	GLPK	MPS/GMPL	OSI/C	none	yes
lp_solve	5.1	lp_solve	MPS/LP/GMPL	C/VB/Java	none	yes
MINTO	3.1	OSI	MPS/AMPL	none	C	yes
SYMPHONY	5.0	OSI	MPS/GMPL	OSI/C	C	yes

Table 1: List of solvers and main features

	Preproc	Built-in Cut Generation	Column Generation	Primal Heuristic	Branching Rules	Search Strategy
ABACUS	no	no	yes	no	f,h,s	b,r,d,2(d,b)
BCP	no	no	yes	no	f,h,s	h(d,b)
bonsaiG	no	no	no	no	p	h(d,b)
CBC	yes	yes	no	yes	e,f,g,h,s,x	2(d,p)
GLPK	no	no	no	no	i,p	b,d,p
lp_solve	no	no	no	no	e,f,i,x	d,r,e,2(d,r)
MINTO	yes	yes	yes	yes	e,f,g,p,s	b,d,e,h(d,e)
SYMPHONY	no	yes	yes	no	e,f,h,p,s	b,r,d,h(d,b)

Table 2: Algorithmic features of solvers

is unlikely that one set of parameters will work best for all classes of MILP instances. When deciding on a MILP package to use, users are well-advised to consider the ability of a packages to meet their performance requirements through customization and parameter tuning. An additional caveat about performance is that MILP solver performance can be affected significantly by the speed with which the LP relaxations are solved, so users may need to pay special attention to the parameter tuning of the underlying LP solver as well.

4.1 ABACUS

4.1.1 Overview

ABACUS [47] is a pure solver framework written in C++. It has a flexible, object-oriented design that supports the implementation of a wide variety of sophisticated and powerful

Name	Knapsack	GUB	Flow	Clique	Implication	Gomory	MIR
CBC	yes	no	yes	yes	yes	yes	yes
MINTO	yes	yes	yes	yes	yes	no	no
SYMPHONY	yes	no	yes	yes	yes	yes	yes

Table 3: Classes of valid inequalities generated by black-box solvers

variants of branch and bound. The object-oriented design of the library is similar in concept to BCP, described below. From the user’s perspective, the framework is centered around C++ objects that represent the basic building blocks of a mathematical model—constraints and variables. The user can dynamically generate variables and valid inequalities by defining classes derived from the library’s base classes. ABACUS supports the simultaneous generation of variables and valid inequalities for users requiring this level of sophistication. Another notable feature of ABACUS is its very general implementation of *object pools* for storing previously generated constraints and variables for later use.

ABACUS was a commercial code for some time, but has recently been released [80] under the open-source GNU Library General Public License (LGPL). Because of the generality of its treatment of dynamically generated classes of constraints and variables, it is one of the most full-featured solver frameworks available. ABACUS does not, however, have a callable library interface and it cannot be used as a black-box solver, though it can be called recursively. It comes with complete documentation and a tutorial that shows how to use the code. Compared to BCP, ABACUS has a somewhat cleaner interface, with fewer classes and a more straightforward object-oriented structure. The target audience for ABACUS consists of sophisticated users who need a powerful framework for implementing advanced versions of branch and bound, but who do not need a callable library interface.

4.1.2 User Interface

There are four main C++ base classes from which the user may derive problem-specific implementations in order to develop a custom solver. The base classes are the following:

- **ABA_VARIABLE**: The base class for defining problem-specific classes of variables.
- **ABA_CONSTRAINT**: The base class for defining problem-specific classes of constraints.
- **ABA_MASTER**: The base class for storing problem data and initializing the root node.
- **ABA_SUB**: The base class for methods related to the processing of a search tree node.

In addition to defining new template classes of constraints and variables, the latter two C++ classes are used to implement various user callback routines to further customize the

algorithm. The methods that can be implemented in these classes are similar to those in other solver frameworks and can be used to customize most aspects of the underlying algorithm.

4.1.3 Algorithm Control

ABACUS does not contain built-in routines for generating valid inequalities, but the user can implement any desirable separation or column generation procedures to improve the **lower bound** in each search tree node. ABACUS does not have a default primal heuristic for improving the **upper bound** either, but again, the user can implement one easily. ABACUS has a general notion of **branching** in which one may branch on either a variable or a constraint (hyperplane). Several strategies for selecting a branching variable are provided. In addition, a strong branching facility is provided, in which a number of variables or constraints are selected and presolved before the final branching is performed. To select the candidates, a sophisticated mechanism for selection and ranking of candidates using multiple user-defined branching rules is employed. The **search strategies** include depth-first, breadth-first, and best-first search, as well as a strategy that switches from depth-first to best-first after the first feasible solution is found.

4.2 BCP

4.2.1 Overview

BCP is a pure solver framework developed by Ladányi. It is a close relative of SYMPHONY, described below. Both frameworks are descendants of the earlier COMPSys framework of Ralphs and Ladányi [48, 68]. Like ABACUS, BCP is implemented in C++ and is designed around problem-specific template classes of cuts and variables, but it takes a more “function-oriented” approach that is similar to SYMPHONY. The design is very flexible and supports the implementation of the same range of sophisticated variants of branch and bound that ABACUS supports, including simultaneous generation of columns and valid inequalities. BCP is a pure solver framework and does not have a callable library interface. The BCP library provides its own main function, which means that it cannot easily be called recursively or as a subroutine from another code. Nonetheless, it is still one of the most full-featured solver frameworks available, because of the generality with which it handles constraint and variable generation, as well as branching.

Although BCP is not itself a black-box solver, two different black-box codes [57] have been built using BCP and are available along with BCP itself as part of the COIN-OR software suite [49]. It is open-source software licensed under the Eclipse Public License (EPL). BCP has a user’s manual, though it is slightly out of date. The code itself contains documentation that can be parsed and formatted using the Doxygen automatic documen-

tation system [83]. A number of applications built using BCP are available for download, including some simple examples that illustrate its use. Tutorials developed by Galati that describe the implementation of two problem-specific solvers—one implementing branch and cut and one implementing branch and price—are also available for download [34]. The target audience for BCP is similar to that of ABACUS—sophisticated users who need a powerful framework for implementing advanced versions of branch and bound without a callable library interface. BCP is also capable of solving MILPs in parallel and is targeted at users who need such a capability.

4.2.2 User Interface

To use BCP, the user must implement application-specific C++ classes derived from the virtual base classes provided as part of the BCP library. The classes that must be implemented fall broadly into two categories: *modeling object classes*, which describe the variables and constraints associated with the user’s application, and *user callback classes*, which control the execution of various specific parts of the algorithm.

From the user’s point of view, a subproblem in BCP consists primarily of a *core relaxation* present in every subproblem and a set of *modeling objects*—the extra constraints and variables that augment the core relaxation. To define new template classes of valid inequalities and variables, the user must derive from the classes `BCP_cut` and `BCP_var`. The derivation involves defining an abstract data structure for describing a member of the class and providing methods for *expanding* each object (i.e., adding the object to a given LP relaxation).

To enable parallel execution, the internal library and the set of user callback functions are divided along functional lines into five separate computational modules. The modular implementation facilitates code maintenance and allows easy, configurable parallelization. The five modules are *master*, *tree manager*, *node processor*, *cut generator*, and *variable generator*. The master module includes functions that perform problem initialization, input/output, and overall execution control. The tree manager is responsible for maintaining the search tree and managing the search process. The node processor is responsible for processing a single search tree node, that is, producing a bound on the solution value of the corresponding subproblem by solving a dynamically generated LP relaxation. Finally, the cut and variable generators are responsible for generating new modeling objects for inclusion in the current LP relaxation.

Associated with each module “**xx**” is a class named `BCP_xx_user` that contains the user callbacks for the module. For each module, the user must implement a derived class that overrides those methods for which the user wishes to provide a customized implementation. Most, but not all, methods have default implementations. The user callback classes can

also be used to store the data needed to execute the methods in the class. Such data could include the original input data, problem parameters, and instance-specific auxiliary information, such as graph data structures.

4.2.3 Algorithm Control

Like ABACUS, BCP does not contain built-in routines for generating valid inequalities, but the user can implement any separation or column generation procedure that is desired in order to improve the **lower bound**. BCP tightens variable bounds on the basis of reduced cost and allows the user to tighten bounds on the basis of logical implications that arise from the model. BCP does not yet have a built-in integer preprocessor and also has no built-in primal heuristic to improve the **upper bound**. The user can, however, pass an initial upper bound if desired. The default **search strategy** is a hybrid depth-first/best-first approach in which one of the children of the current node is retained for processing as long as the lower bound is not more than a specified percentage higher than the best available. The user can also specify a customized search strategy by implementing a new comparison function for sorting the list of candidate nodes in the `BCP_tm_user` class.

BCP has a generalized **branching** mechanism in which the user can specify *branching sets*, that consist of any number of hyperplanes and variables. The hyperplanes and variables in these branching sets do not have to be present in the current subproblem. In other words, one can branch on any arbitrary hyperplane (see Section 2.3), whether or not it corresponds to a known valid inequality. After the desired candidate branching sets have been chosen, each one is presolved as usual by performing a specified number of simplex pivots to estimate the bound improvement that would result from the branching. The final branching candidate can then be chosen by a number of standard built-in rules. The default rule is to select a candidate for which the smallest lower bound among its children is maximized.

4.3 BonsaiG

4.3.1 Overview

BonsaiG is a pure black-box solver developed by Lou Hafer that comes with complete documentation and descriptions of its algorithms and is available as open-source software under the GNU General Public License (GPL) [42]. BonsaiG does not have a documented callable library interface or the customization options associated with a solver framework. It does, however, have two unique features worthy of mention. The first is the use of a partial arc consistency algorithm proposed in [79] to help enforce integrality constraints and dynamically tighten bounds on variables. Although the approach is similar to that taken by today's integer programming preprocessors, the arc consistency algorithm can be seen

as a constraint programming technique and is applied aggressively during the processing of each subproblem. From this perspective, bonsaiG is perhaps one of the earliest examples of integrating constraint programming techniques into an LP-based branch-and-bound algorithm. The integration of constraint programming and traditional mathematical programming techniques has recently become a topic of increased interest among researchers. Achterberg is currently developing a solver called SCIP that will also integrate these two approaches [1].

The second feature worthy of mention is the use of DYLP, an implementation of the dynamic LP algorithm of Padberg [67], as the underlying LP solver. DYLP was designed specifically to be used for solving the LP relaxations arising in LP-based branch and bound. As such, DYLP automatically selects the subsets of the constraints and variables that should be active in a relaxation and manages the process of dynamically updating the active constraints and variables as the problem is solved. This management must be performed in some fashion by all MILP solvers, but it can be handled more efficiently if kept internal to the LP solver. The target audience for bonsaiG consists of users who need a lightweight black-box solver capable of solving relatively small MILPs without incurring the overhead associated with advanced bounding techniques and those who do not need a callable library interface.

4.3.2 User Interface and Algorithm Control

BonsaiG can only be called from the command-line, with instances specified in MPS format. Algorithm control in bonsaiG is accomplished through the setting of parameters that are specified in a separate file. To improve the **lower bound** for generic MILPs, bonsaiG aggressively applies the arc consistency algorithm discussed earlier in combination with tightening of bounds on the basis of reduced cost in an iterative loop called the *integrated variable forcing loop*. No generation of valid inequalities or columns is supported. BonsaiG does not have any facility for improving the **upper bound**. The default **search strategy** is a hybrid of depth-first and best-first, but with a slight modification. When a subproblem is partitioned, all children are fully processed and among those that are not fathomed, the best one, according to an evaluation function that takes into account both the lower bound and the integer infeasibility, is retained for further partitioning. The others are added to the list of candidates, so that the list is actually one of candidates for branching, rather than for processing. When all children of the current node can be fathomed, then the candidate with the best bound is retrieved from the list and another depth-first search is initiated.

For **branching**, BonsaiG uses a penalty method strengthened by integrality considerations. Only branching on variables or groups of variables is supported. The user can influence branching decisions for a particular instance or develop custom branching strate-

gies through two different mechanisms. First, `bonsaiG` makes the specification of relative branching priorities for groups of variables easy. This tells the solver which variables the user thinks will have the most effect if branched upon. The solver then attempts to branch on the highest-priority fractional variables first. The second mechanism is for specifying *tours* of variables. Tours are groups of variables that should be branched on as a whole. The group of child subproblems (called a *tour group*) is generated by adjustment of the bounds of each variable in the tour so that the feasible region of the parent is contained in the union of the feasible regions of the children, as usual.

4.4 CBC

4.4.1 Overview

CBC is a black-box solver distributed as part of the COIN-OR software suite [30]. CBC was originally developed by John Forrest as a lightweight branch-and-cut code to test CLP, the COIN-OR LP solver. However, CBC has since evolved significantly and is now quite sophisticated, even sporting customization features that allow it to be considered a solver framework. CBC has a native C++ callable library API similar to the Open Solver Interface, as well as a C interface built on top of that native interface. The CBC solver framework consists of a collection of C++ classes whose methods can be overridden to customize the algorithm. CBC does not have a user's manual, but it does come with some well-commented examples and the source code is also well-commented. It is distributed as part of the COIN-OR software suite and is licensed as open-source software under the Eclipse Public License (EPL). The target audience for CBC consists of users who need a full-featured black-box solver with a callable library API and very flexible, yet relatively lightweight, customization options.

4.4.2 User Interface

The user interacts with CBC as a black-box solver either by invoking the solver on the command line or through a command-based interactive shell. In either case, instances must be specified in MPS format. The callable library API is a hybrid of the API of the underlying LP solver, which is accessed through the Open Solver Interface, and the methods in the `CbcModel` class. To load a model into CBC, the user creates an OSI object, loads the model into the OSI object and then passes a pointer to that object to the constructor for the `CbcModel` object. CBC uses the OSI object as its LP solver during the algorithm.

To use CBC as a solver framework, a number of classes can be reimplemented to arrive at a problem-specific version of the basic algorithm. The main classes in the CBC library are:

- `CbcObject`, `CbcBranchingObject`, and `CbcBranchDecision`: The classes used to specify new branching rules. CBC has a very general notion of branching that is similar to that of BCP. CBC's branching mechanism is described in more detail in Section 4.4.3.
- `CbcCompare` and `CbcCompareBase`: The classes used to specify new search strategies by specifying the method for sorting the list of candidate search tree nodes.
- `CbcHeuristic`: The class used to specify new primal heuristics.
- `CbcCutGenerator`: The class that interfaces to the Cut Generation Library.

As seen from the above list, custom branching rules, custom search strategies, custom primal heuristics, and custom generators for valid inequalities can all be introduced. Cut generator objects must be derived from the Cut Generation Library base class and are created by the user before they are passed to CBC. Primal heuristic objects are derived from the `CbcHeuristic` class and are also created before being passed to CBC.

4.4.3 Algorithm Control

CBC is one of the most full-featured black-box solvers of those reviewed here in terms of available techniques for improving bounds. The **lower bound** can be improved through the generation of valid inequalities using all of the separation algorithms implemented in the CGL. Problem-specific methods for generation of valid inequalities can be implemented, but column generation is not supported. CBC has a logical preprocessor to improve the initial model and tightens variable bounds using reduced cost information. Several primal heuristics to improve the **upper bound** are implemented and provided as part of the distribution, including a rounding heuristic and two different local search heuristics. The default **search strategy** in CBC is to perform depth-first search until the first feasible solution is found and then to select nodes for evaluation on the basis of a combination of bound and number of unsatisfied integer variables. Specification of new search strategies can also be accomplished easily.

CBC has a strong **branching** mechanism similar to that of other solvers, but the type of branching that can be done is more general. An abstract CBC branching object can be anything that (1) has a feasible region whose degree of infeasibility with respect to the current solution can be quantified, (2) has an associated action that can be taken to improve the degree of infeasibility in the child nodes, and (3) supports some comparison of the effect of branching. Specification of a CBC branching object involves implementation of three methods: `infeasibility()`, `feasibleRegion()`, and `createBranch()`. These methods allow CBC to perform strong branching on any sort of branching objects. Default implementations are provided for branching on integer variables, branching on cliques, and branching on special ordered sets.

4.5 GLPK

4.5.1 Overview

GLPK is the GNU Linear Programming Kit, a set of subroutines that comprises a callable library and black-box solver for solving linear programming and MILP instances [54]. GLPK also comes equipped with GNU MathProg (GMPL), an algebraic modeling language similar to AMPL. GLPK was developed by Andrew Makhorin and is distributed as part of the GNU Project, under the GNU General Public License (GPL). Because GLPK is distributed through the Free Software Foundation (FSF), it closely follows the guidelines of the FSF with respect to documentation and automatic build tools. The build system relies on `autoconf`, which ensures that users can easily build and execute the library on a wide variety of platforms. The documentation consists of a reference manual and a description of the GNU MathProg language. The distribution includes examples of the use of the callable library and models that demonstrate the MathProg language.

GLPK is a completely self-contained package that does not rely on external components to perform any part of the branch-and-bound algorithm. In particular, GLPK includes the following main components:

- revised primal and dual simplex methods for linear programming,
- a primal-dual interior point method for linear programming,
- a branch-and-bound method,
- a parser for GNU MathProg,
- an application program interface (API), and
- a black-box LP/MILP solver.

The target audience for GLPK consists of users who want a lightweight, self-contained MILP solver with both a callable library and modeling language interface.

4.5.2 User Interface

The default build of GLPK yields the callable library and a black-box solver. The callable library consists of nearly 100 routines for loading and modifying a problem instance, solving the loaded instance, querying the solver, and getting and setting algorithm parameters. There are also utility routines to read and write files in MPS format, LP format, and GMPL format. The subroutines operate on a data structure for storing the problem instance that is passed explicitly, so the code is thread safe and it is possible to work on multiple models simultaneously.

4.5.3 Algorithm Control

Because GLPK was first and foremost developed as a solver of linear programs, it does not yet contain advanced techniques for improving the **lower bound**, such as those for preprocessing and generating valid inequalities. It also does not include a primal heuristic for improving the **upper bound**. The user can set a parameter (either through the callable library or in the black-box solver) to choose from one of three methods for selecting a **branching** variable—the index of the first fractional variable, the index of the last fractional variable, or the penalty method discussed in Section 2.3. The user can change the **search strategy** to either depth-first-search, breadth-first-search, or the best-projection method described in Section 2.4.

4.6 lp_solve

4.6.1 Overview

Lp_solve is a black-box solver and callable library for linear and mixed-integer programming. The original solver was developed by Michel Berkelaar at Eindhoven University of Technology, and the work continued with Jeroen Dirks, who contributed a procedural interface, a built-in MPS reader, and fixes and enhancements to the code. Kjell Eikland and Peter Notebaert took over development starting with version 4. There is currently an active group of users. The most recent version bears little resemblance to earlier versions and includes a number of unique features, such as a modular LP basis factorization engine and a large number of language interfaces. Lp_solve is distributed as open-source software under the GNU Library General Public License (LGPL). The main repository for lp_solve information, including a FAQ, examples, the full source, precompiled executables, and a message board, is available at the YAHOO lp_solve group [15]. The target audience for lp_solve is similar to that of GLPK—users who want a lightweight, self-contained solver with a callable library API implemented in a number of popular programming languages, including C, VB, and Java, as well as an AMPL interface.

4.6.2 User Interface

Lp_solve can be used as a black-box solver or as a callable library through its native C API. The lp_solve API consists of over 200 functions for reading and writing problem instances, building or querying problem instances, setting algorithm parameters, invoking solution algorithms, and querying the results. The lp_solve API has methods that can read and write MPS files, LP format files, and an XLI (External Language Interface) that allows users to implement their own readers and writers. At present, XLI interfaces are in place for GNU MathProg, LPFML, and for the commercial LP formats of CPLEX and LINDO.

An interface to ZIMPL will be available in lp_solve v5.2.

Of the noncommercial MILP software reviewed here, lp_solve has interfaces to the largest number of different programming languages. With lp_solve, there are examples that illustrate how to call its API from within a VB.NET or C# program. A Delphi library and a Java Native Interface (JNI) to lp_solve are available, so lp_solve can be called directly from Java programs. AMPL, MATLAB, R, S-Plus and Excel driver programs are also available. Lp_solve supports several types of user callbacks and an object-like facility for revealing functionality to external programs.

4.6.3 Algorithm Control

Lp_solve does not have any special procedures for improving the **upper** or **lower bounds**. Users can set parameters either from the command line or through the API to control the branch-and-bound procedure. The **search strategy** is one of depth-first search, breadth-first search, or a two-phase method that initially proceeds depth-first, followed by breadth-first. Lp_solve contains a large number of built-in **branching** procedures and can select the branching variable on the basis of the lowest indexed non-integer column (default), the distance from the current bounds, the largest current bound, the most fractional value, the simple, unweighted pseudocost of a variable, or pseudocosts combined with the number of integer infeasibilities.

The algorithm also allows for GUB branching and for branching on semi-continuous variables (variables that have to take a value of zero or a positive value above some given lower bound). The branching rule and search strategy used by lp_solve is set through a call to `set_bb_rule()`, and the branching rule can even be modified using parameter values beyond those listed here. As with many MILP solvers, performance can be expected to vary significantly based on parameters settings and model class. The default settings in lp_solve are inherited from v3.2, and tuning is therefore necessary to achieve desirable results. The developers have indicated that performance improvement and more robust default settings will be a focus in lp_solve v5.3.

4.7 MINTO

4.7.1 Overview

MINTO (Mixed INTeger Optimizer) is a black-box solver and solver framework whose chief architects were George Nemhauser and Martin Savelsbergh, with a majority of the software development done by Savelsbergh. MINTO was developed at the Georgia Institute of Technology and is available in binary form under terms of an agreement created by the Georgia Tech Research Institute. The current maintainer of MINTO is Jeff Linderoth of Lehigh University. MINTO is available only as a precompiled library for a number of

common platforms [61]. MINTO relies on external software to solve the linear programming relaxations that arise during the algorithm. Since version 3.1, MINTO has been equipped to use the OSI, so any of the linear programming solvers for which there is an OSI interface can be used with MINTO. MINTO can also be built to directly use the commercial LP solvers CPLEX, XPRESS-MP, and OSL. MINTO comes with a user’s manual that contains instructions for building an executable, a description of the API for user callbacks that allow it to be used as a solver framework, and examples of the use of each routine. The target audience for MINTO are users who require the power of a sophisticated solver framework for implementing advanced versions of branch and bound, but with a relatively simple C-style interface, or who need a full-featured black-box solver without a callable API.

4.7.2 User Interface

MINTO can be accessed as a black-box solver from the command line with parameters set through a number of command-line switches. The most common way of using MINTO is to pass problem instances in MPS file format. However, beginning with version 3.1, MINTO can also be used directly with the AMPL modeling language. MINTO can be customized through the use of “user application” functions (callback functions) that allow MINTO to operate as a solver framework. At well-defined points of the branch-and-cut algorithm, MINTO will call the user application functions, and the user must return a value that signals to MINTO whether or not the algorithm is to be modified from the default. For example, consider the MINTO user application function `appl_constraints()`, which is used for generating user-defined classes of valid inequalities. The input to `appl_constraints()` is the solution to the current LP relaxation. The outputs are arrays describing any valid inequalities that the user wishes to have added to the formulation. The return value from `appl_constraint()` should be `SUCCESS` or `FAILURE`, depending on whether or not the user-supplied routine was able to find inequalities violated by the input solution. If so, MINTO will add these inequalities and pass the new formulation to the linear programming solver.

4.7.3 Algorithm Control

To strengthen the **lower bound** during the course of the algorithm, MINTO relies on advanced preprocessing and probing techniques, as detailed in the paper of Atamtürk, Nemhauser, and Savelsbergh [5], and also tightens bounds on the basis of reduced cost. MINTO has separation routines for a number of classes of valid inequalities, including clique inequalities, implication inequalities, knapsack cover inequalities, GUB cover inequalities, and flow cover inequalities. The user can perform dynamic column generation by implementing the callback function `appl_variables()`. For improving the **upper bound**, MINTO has a primal diving heuristic. A number of built-in **branching** methods are included, such

as branching on the most fractional variable, a penalty method strengthened with integrality considerations, strong branching, a pseudocost-based method, a dynamic method that combines both the penalty method and pseudocost-based branching, and a method that favors branching on GUB constraints. For **search strategies**, the user can choose best-bound, depth-first, best-projection, best-estimate, or an adaptive mode that combines depth-first with the best-estimate mode. Of course, by using the solver framework, the user can override any of the branching or node selection methods.

4.8 SYMPHONY

4.8.1 Overview

SYMPHONY is a black-box solver, callable library, and solver framework for MILPs that evolved from the COMPSys framework of Ralphs and Ladányi [48, 68]. The source code for packaged releases, with full documentation and examples, is available and is licensed under the Eclipse Public License (EPL) [72]. The latest source is also available from the CVS repository of the COIN-OR Foundation [19]. SYMPHONY is fully documented and seven different specialized solvers built with SYMPHONY are available as examples of how to use the code. A step by step example illustrates the construction of a simple branch-and-cut solver in SYMPHONY for the matching problem [82] is available and is summarized in Section 5. The core solution methodology of SYMPHONY is a highly customizable branch-and-bound algorithm that can be executed sequentially or in parallel [73]. SYMPHONY calls on several other open source libraries for specific functionality, including COIN-OR's Cut Generation Library, Open Solver Interface, and MPS file parser components, GLPK's GMPL file parser, and a third-party solver for linear-programming problems (LPs), such as COIN-OR's LP Solver (CLP).

Several unique features of SYMPHONY are worthy of mention. First, SYMPHONY contains a generic implementation of the WCN algorithm described in [74] for solving bi-criteria MILPs, and methods for approximating the set of Pareto outcomes. The bicriteria solver can be used to examine tradeoffs between competing objectives, and for solving parametric MILPS, a form of global sensitivity analysis. SYMPHONY also contains functions for local sensitivity analysis based on ideas suggested by Schrage and Wolsey [77]. Second, SYMPHONY has the capability to warm start the branch-and-bound process from a previously calculated branch-and-bound tree, even after modifying the problem data. These capabilities are described in more detail in the paper of Ralphs and Guzelsoy [71]. The target audience for SYMPHONY is similar to that of MINTO—users who require the power of a sophisticated solver framework, primarily for implementing custom branch and cut algorithms, with a relatively simple C-style interface, or users who require other advanced features such as parallelism, the ability to solve multi-criteria instances, or the ability to

warm start solution procedures.

4.8.2 User Interface

As a black-box solver, SYMPHONY can read GMPL files using an interface to GLPK's file parser or MPS files using COIN-OR's MPS file reader class. It can also be used as a callable library through the API described below. SYMPHONY's callable library consists of a complete set of subroutines for loading and modifying problem data, setting parameters, and invoking solution algorithms. The user invokes these subroutines through the native C API, which is exactly the same whether SYMPHONY is invoked sequentially or in parallel. The choice between sequential and parallel execution modes is made at compile-time. SYMPHONY has an OSI implementation that allows solvers built with SYMPHONY to be accessed through the OSI.

The user's main avenues for customization are the tuning of parameters and the implementation of SYMPHONY's callback functions. SYMPHONY contains over 50 callback functions that allow the user to override SYMPHONY's default behavior for branching, generation of valid inequalities, management of the cut pool, management of the LP relaxation, search and diving strategies, program output, and others. Each callback function is called from a SYMPHONY *wrapper function* that interprets the user's return value and determines what action should be taken. If the user performs the required function, the wrapper function exits without further action. If the user requests that SYMPHONY perform a certain default action, then this is done. Files that contain default function stubs for the callbacks are provided along with the SYMPHONY source code. These can then be modified by the user as desired. Makefiles and Microsoft Visual C++ project files are provided for automatic compilation. A full list of callback functions is contained in the user's manual [69]. For an example of the use of callbacks, see the SYMPHONY case study in Section 5.1.

4.8.3 Algorithm Control

To improve the **lower bound** for generic MILPs, SYMPHONY generates valid inequalities using COIN-OR's Cut Generation Library (CGL) described in Section 2.1.2. The user can easily insert custom separation routines and can perform column generation, although the implementation is not yet fully general and requires that the set of variables be indexed a priori. This limitation makes the column generation in SYMPHONY most appropriate for situations in which the set of columns has a known combinatorial structure and is of relatively small cardinality. In each iteration, SYMPHONY tightens bounds by reduced cost and also allows the user to tighten bounds on the basis of logical implications arising from the model. SYMPHONY does not yet have its own logical preprocessor or primal heuristics

to improve the **upper bound**, although it is capable of using CBC’s primal heuristics if desired. The user can also pass an initial upper bound.

SYMPHONY uses a strong **branching** approach by default. Branching candidates can be either constraints or variables and are chosen by any one of a number of built-in rules, such as most fractional, or by a customized rule. After the candidates are chosen, each one is presolved to determine an estimate of the bound improvement that would result from the branching. The final branching candidate can then be chosen by a number of standard built-in rules. A naive version of pseudocost branching is also available.

The default **search strategy** is a hybrid depth-first/best-first approach in which one of the children of the current node is retained for processing as long as the lower bound is not more than a specified percentage higher than the best available. Another option is to stop diving when the current node is more than a specified percentage of the gap higher than the best available. By tuning various parameters, one can obtain a number of different search strategies that run the gamut between depth-first and best-first.

5 Case Studies

In this section, we describe two examples that illustrate the power of solver frameworks for developing custom optimization codes. In Section 5.1, we describe the implementation of a custom branch-and-cut algorithm for solving the matching problem developed using SYMPHONY. Section 5.2, we describe the implementation of a custom branch-and-price algorithm for the axial assignment problem developed using BCP. Full source code and more detailed descriptions of both solvers are available [34, 82].

5.1 Branch and Cut

The Matching Problem. Given a complete, undirected graph $G = (V, E)$, the *Matching Problem* is that of selecting a set of pairwise disjoint edges of minimum weight. The problem can be formulated as follows:

$$\min \sum_{e \in E} c_e x_e$$

$$\sum_{e \in \{(i,j) \mid j \in V, \{i,j\} \in E\}} x_e = 1 \quad \forall i \in V, \tag{12}$$

$$x_e \geq 0 \quad \forall e \in E, \tag{13}$$

$$x_e \in \mathbb{Z} \quad \forall e \in E,$$

where x_e is a binary variable that takes value 1 if edge e is selected and 0 otherwise.

```

typedef struct MATCH_DATA{
    int          numnodes;
    int          cost[MAXNODES][MAXNODES];
    int          endpoint1[MAXNODES*(MAXNODES-1)/2];
    int          endpoint2[MAXNODES*(MAXNODES-1)/2];
    int          index[MAXNODES][MAXNODES];
}match_data;

```

Figure 1: Data structure for matching solver

Implementing the Solver. The first thing needed is a data structure in which to store the description of the problem instance and any other auxiliary information required to execute the algorithm. Such a data structure is shown in Figure 1. We assume a complete graph, so a problem instance can be described simply by the objective function coefficients, stored in the two-dimensional array `cost`. Each primal variable is identifiable by an index, so we must have a way of mapping an edge $\{i, j\}$ to the index that identifies the corresponding variable and vice versa. Such mappings between problem instance objects and variable indices are a common construct when using solver frameworks, though recent commercial modeling frameworks such as Concert [46] and Mosel [20] and the noncommercial modeling system FLOPC++ [45] have an interface that allows for a more explicit coupling of problem objects and instance variables. In the data structure shown, `endpoint1[k]` returns the first endpoint of the edge with index `k` and `endpoint2[k]` returns the second endpoint. On the other hand `index[i][j]` returns the index of edge $\{i, j\}$.

Next, functions for reading in the problem data and creating the instance are needed. The function `match_read_data()` (not shown) reads the problem instance data (a list of objective function coefficients) in from a file. The function `match_load_problem()`, shown in Figure 2, constructs the instance in column-ordered format. In the first part of this routine, a description of the MILP is built, while in the second part, this representation is loaded through the subroutine `sym_explicit_load_problem()` into the solver.

The `main()` routine for the solver is shown in Figure 3. In this routine, a SYMPHONY environment and a user data structure are created, the data are read in, the MILP is created and loaded into SYMPHONY, and then an instance is solved. Results are automatically printed, but one could also implement a custom subroutine for displaying these if desired.

We next show how to add the ability to generate some simple problem-specific valid inequalities. The odd-set inequalities

$$\sum_{e \in E(O)} x_e \leq \frac{|O| - 1}{2} \quad O \subseteq V, |O| \text{ odd}, \quad (14)$$

```

int match_load_problem(sym_environment *env, match_data *prob){
    int i, j, index, n, m, nz, *column_starts, *matrix_indices;
    double *matrix_values, *lb, *ub, *obj, *rhs, *rngval;
    char *sense, *is_int;

    n = prob->numnodes*(prob->numnodes-1)/2; /* Number of columns */
    m = 2 * prob->numnodes;                  /* Number of rows */
    nz = 2 * n;                              /* Number of nonzeros */
    /* Normally, allocate memory for the arrays here (left out to save space) */
    for (index = 0, i = 0; i < prob->numnodes; i++) {
        for (j = i+1; j < prob->numnodes; j++) {
            prob->match1[index] = i; /*The 1st component of assignment 'index'*/
            prob->match2[index] = j; /*The 2nd component of assignment 'index'*/
            prob->index[i][j] = prob->index[j][i] = index; /*To recover later*/
            obj[index] = prob->cost[i][j]; /* Cost of assignment (i, j) */
            is_int[index] = TRUE; /* Indicates the variable is integer */
            column_starts[index] = 2*index;
            matrix_indices[2*index] = i;
            matrix_indices[2*index+1] = j;
            matrix_values[2*index] = 1;
            matrix_values[2*index+1] = 1;
            ub[index] = 1.0;
            index++;
        }
    }
    column_starts[n] = 2 * n; /* We have to set the ending position */
    for (i = 0; i < m; i++) { /* Set the right-hand side */
        rhs[i] = 1;
        sense[i] = 'E';
    }
    sym_explicit_load_problem(env, n, m, column_starts, matrix_indices,
                             matrix_values, lb, ub, is_int, obj, 0, sense, rhs,
                             rngval, true);
    return (FUNCTION_TERMINATED_NORMALLY);
}

```

Figure 2: Function to load the problem for matching solver

```

int main(int argc, char **argv)
{
    int termcode;
    char * infile;

    /* Create a SYMPHONY environment */
    sym_environment *env = sym_open_environment();

    /* Create the data structure for storing the problem instance.*/
    user_problem *prob = (user_problem *)calloc(1, sizeof(user_problem));

    sym_set_user_data(env, (void *)prob);
    sym_parse_command_line(env, argc, argv);
    sym_get_str_param(env, "infile_name", &infile);
    match_read_data(prob, infile);
    match_load_problem(env, prob);
    sym_solve(env);
    sym_close_environment(env);
    return(0);
}

```

Figure 3: Main function for the matching solver

with $E(O) = \{e = \{i, j\} \in E \mid i \in O, j \in O\}$ are satisfied by all matchings. Indeed, Edmonds [28] showed that the inequalities (12), (13), and (14) describe the convex hull of matchings, so the matching problem can, in theory, be solved as a linear program, albeit with an exponential number of constraints.

The textbook of Grötschel, Lovász, and Schrijver [38] describes how to efficiently separate the odd-set inequalities in full generality, but for simplicity, we implement separation only for odd-set inequalities for sets O of cardinality three. This is done by brute force enumeration of triples, as shown in Figure 4. The function `user_find_cuts()` is the SYMPHONY callback for generating valid inequalities. The user is provided with the current fractional solution in a sparse vector format and asked to generate violated valid inequalities. The function `cg_add_explicit_cut()`, is used to report any inequalities found. Even this simple separation routine can significantly reduce the number of nodes in the branch-and-cut tree.

```

int user_find_cuts(void *user, int varnum, int iter_num, int level,
                  int index, double objval, int *indices, double *values,
                  double ub, double etol, int *num_cuts, int *alloc_cuts,
                  cut_data ***cuts)
{
    user_problem *prob = (user_problem *) user;
    double cut_val[3], edge_val[200][200]; /* Matrix of edge values */
    int i, j, k, cutind[3], cutnum = 0;

    /* Allocate the edge_val matrix to zero (we could also just calloc it) */
    memset((char *)edge_val, 0, 200*200*ISIZE);

    for (i = 0; i < varnum; i++) {
        edge_val[prob->node1[indices[i]]][prob->node2[indices[i]]] = values[i];
    }
    for (i = 0; i < prob->nnodes; i++){
        for (j = i+1; j < prob->nnodes; j++){
            for (k = j+1; k < prob->nnodes; k++) {
                if (edge_val[i][j]+edge_val[j][k]+edge_val[i][k] > 1.0 + etol) {
                    /* Found violated triangle cut */
                    /* Form the cut as a sparse vector */
                    cutind[0] = prob->index[i][j];
                    cutind[1] = prob->index[j][k];
                    cutind[2] = prob->index[i][k];
                    cutval[0] = cutval[1] = cutval[2] = 1.0;
                    cg_add_explicit_cut(3, cutind, cutval, 1.0, 0, 'L',
                                      TRUE, num_cuts, alloc_cuts, cuts);

                    cutnum++;
                }
            }
        }
    }
    return(USER_SUCCESS);
}

```

5.2 Branch and Price

The Three-Index Assignment Problem. The *Three-Index Assignment Problem* (3AP) is that of finding a minimum-weight clique cover of the complete tri-partite graph $K_{n,n,n}$, where n is defined here to indicate the size of the underlying graph. Let I, J and K be three disjoint sets with $|I| = |J| = |K| = n$ and set $H = I \times J \times K$. Then, 3AP can be formulated as follows:

$$\begin{aligned} \min \quad & \sum_{(i,j,k) \in H} c_{ijk} x_{ijk}, \\ & \sum_{(j,k) \in J \times K} x_{ijk} = 1 \quad \forall i \in I, \end{aligned} \tag{15}$$

$$\begin{aligned} & \sum_{(i,k) \in I \times K} x_{ijk} = 1 \quad \forall j \in J, \\ & \sum_{(i,j) \in I \times J} x_{ijk} = 1 \quad \forall k \in K, \end{aligned} \tag{16}$$

$$x_{ijk} \in \{0, 1\} \quad \forall (i, j, k) \in H.$$

In [10], Balas and Saltzman consider the use of the classical Assignment Problem (AP) as a relaxation of 3AP in the context of Lagrangian relaxation. We use the same relaxation to reformulate the 3AP using a Dantzig-Wolfe decomposition (see Section 2.1.4 for a discussion of this technique). The AP is a relaxation of the 3AP obtained by relaxing constraint (15). Let \mathcal{F} be the set of feasible solutions to the AP. The Dantzig Wolfe (DW) reformulation of 3AP is then:

$$\begin{aligned} \min \quad & \sum_{s \in \mathcal{F}} c_s \lambda_s, \\ & \sum_{s \in \mathcal{F}} \left(\sum_{(j,k) \in J \times K} s_{ijk} \lambda_s \right) = 1 \quad \forall i \in I, \\ & \sum_{s \in \mathcal{F}} \lambda_s = 1, \\ & \lambda_s \in \mathbb{Z}_+ \quad \forall s \in \mathcal{F}, \end{aligned}$$

where $c_s = \sum_{(i,j,k) \in H} c_{ijk} s_{ijk}$ for each $s \in \mathcal{F}$. Relaxing the integrality constraints of this reformulation, we obtain a relaxation of 3AP suitable for use in an LP-based branch-and-bound algorithm. Because of the exponential number of columns in this linear program, we use a standard column generation approach to solve it.

Implementing the Solver. The main classes to be implemented are the `BCP_xx_user` classes mentioned earlier and a few problem-specific classes. We describe the problem-specific classes first.

- `AAP`: This class is a container for holding an instance of 3AP. Data members include the dimension of the problem n and the objective function vector.
- `AAP_user_data`: This class is derived from `BCP_user_data` and is used to store problem-specific information in the individual nodes of the search tree. Because we branch on the original variables x_{ijk} and not the master problem variables λ_s , we must keep track of which variables have been fixed to 0 or 1 at a particular node, so that we can enforce these conditions in our column generation subproblem.
- `AAP_var`: Each variable in the Dantzig-Wolfe reformulation represents an assignment between members of sets J and K . In each instance of the class, the corresponding assignment is stored using a vector that contains the indices of the assignment along with its cost.

Because `BCP` is a parallel code, every data structure must be accompanied by a subroutine that can both pack it into and unpack it from a character buffer for the purposes of communicating the contents to other parallel processes. For most built-in types, default pack and unpack routines are predefined. For user-defined data structures, however, they must be provided. Typically, such routines consist simply of a collection of calls to either `BCP_buffer::pack()` or `BCP_buffer::unpack()`, as appropriate, which pack or unpack each data member of the class in turn. The user callback classes that must be modified are as follows.

- `AAP_tm`: This class is derived from `BCP_tm_user` and contains the callbacks associated with initialization and tree management. The main callbacks implemented are `initialize_core()` and `create_root()`. These methods define the core relaxation and the initial LP relaxation in the root node.
- `AAP_lp`: This class is derived from `BCP_lp_user` and contains the callbacks associated with the solution of the LP relaxations in each search tree node. The main methods implemented are

`generate_vars_in_lp()`: the subroutine that generates new variables,

`compute_lower_bound()`: returns a true lower bound in each iteration (the LP relaxation does not yield a true lower bound unless no variables with negative reduced cost exist),

`restore_feasibility()`: a subroutine that tries to generate columns that can be used to restore the feasibility of a relaxation that is currently infeasible,

`vars_to_cols()`: a subroutine that generates the columns corresponding to a set of variables, so that they can be added to the current relaxation,

`select_branching_candidates()`: a subroutine that selects candidates for strong branching. We branch on the original variables x_{ijk} . Candidates are selected by the usual “most fractional” rule using the helper function `branch_close_to_half()`. A second function, `append_branching_vars()`, is called to create the branching objects, and

`set_user_data_for_children()`: Stores the appropriate data regarding what original variables were branched on in each child node.

In addition to defining these classes, a few important parameters must be set. We have glossed over some details here, but the source code and a more thorough description of this example are available for download [34].

6 Benchmarking

In this section, we present computational results that show the relative performance of the black-box solvers reviewed in Section 4. Each solver was built with gcc 3.3 using the default build parameters. The experiments were run under Linux RedHat v7.3 on an Intel Pentium III with an 1133MHz clock speed and 512MB of memory. The maximum CPU time allowed for each solver and each instance was two hours. For each of the codes, the default parameter settings were used on the instances, except for `lp_solve`, in which the default branching and node selection rules were changed to ones based on pseudocost².

There were 122 problem instances included in the test: the instances of `miplib3`³[16], `miplib2003` [58], and 45 instances collected by the authors from various sources. The instances collected by the authors are available from the Computational Optimization Research at Lehigh (COR@L) Web site [51]. Table 4 shows the number of rows m , number of variables n , number of continuous variables $n - p$, number of binary variables $|B|$, and number of general integer variables $p - |B|$ for each instance in the test suite that is not already available through MIPLIB.

²The `lp_solve` command line was: `lp_solve -mps name.mps -bfp ./bfp_LUSOL -timeout 7200 -time -presolve -presolve1 -piva -piv1a -piv2 -ca -B5 -Bd -Bg -si -s5 -se -degen -S1 -v4`.

³With the exception of the simple instances `air03`, `blend2`, `egout`, `enigma`, `flugpl`, `gen`, `khh05250`, `lseu`, `misc03`, `misc06`, `mod008`, `mod010`, `p0033`, `p0201`, `p0282`, `rgn`, `stein27`, `vpm1`, which at least 5 of the six solvers were able to solve in less than 2 minutes.

Table 4: Characteristics of (non MIPLIB) problem instances

In order to succinctly present the results of this extensive computational study, we use performance profiles, as introduced by Dolan and Moré [25]. A performance profile is a relative measure of the effectiveness of a solver s when compared to a group of solvers \mathcal{S} on a set of problem instances P . To completely specify a performance profile, we need the following definitions:

- γ_{ps} is a quality measure of solver s when solving problem p ,
- $r_{ps} = \gamma_{ps} / (\min_{s \in \mathcal{S}} \gamma_{ps})$, and
- $\rho_s(\tau) = |\{p \in P \mid r_{ps} \leq \tau\}| / |P|$.

Hence, $\rho_s(\tau)$ is the fraction of instances for which the performance of solver s was within a factor of τ of the best. A performance profile for solver s is the graph of $\rho_s(\tau)$. In general, the “higher” the graph of a solver, the better the relative performance.

Comparison of MILP solvers directly on the basis of performance is problematic in a number of ways. By compiling these codes with the same compiler on the same platform and running them under identical conditions, we have eliminated some of the usual confounding variables, but some still remain. One important consideration is the feasibility, optimality, and integrality tolerances used by the solver. Dolan, Moré, and Munson [24] performed a careful study of the tolerances used in nonlinear programming software and concluded that trends of the performance profile tend to remain the same when tolerances are varied. The

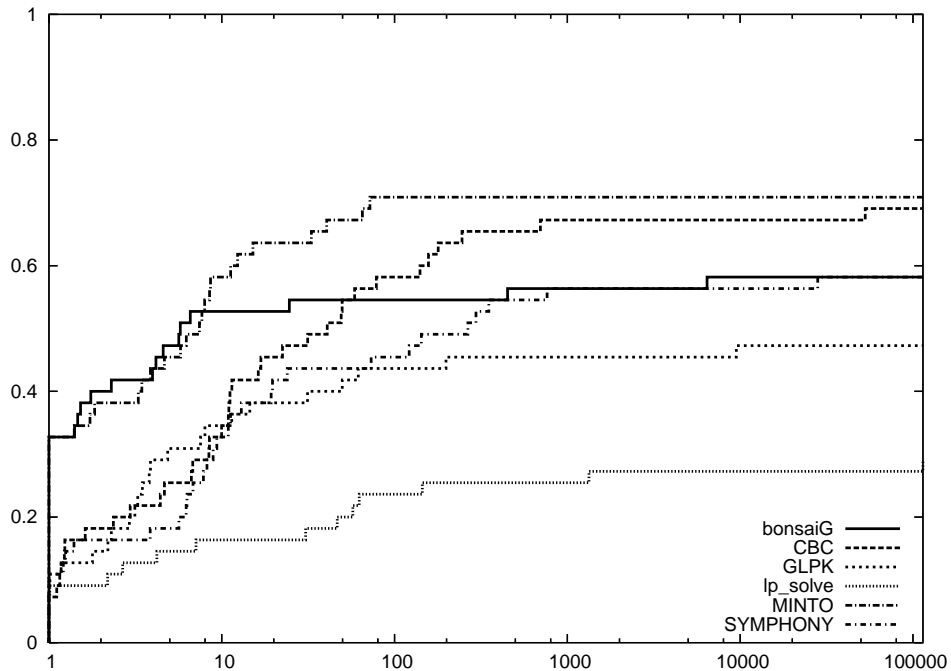

Figure 5: Performance Profile of MILP Solvers on Solved Instances

differences in solver tolerances for these tests were relatively minor, but these minor differences could lead to large differences in runtime performance. Another potential difficulty is the verification of solvers' claims with respect to optimality and feasibility of solutions. The authors made little attempt to verify *a posteriori* that the solutions claimed as optimal or feasible were indeed optimal or feasible. The conclusions drawn here about the relative effectiveness of the MILP solvers must be considered with these caveats in mind.

For instances that were solved to provable optimality by one of the six solvers, the solution time was used as the quality measure γ_{ps} . Under this measure, $\rho_s(1)$ is the fraction of instances for which solver s was the fastest solver, and $\rho_s(\infty)$ is the fraction of instances for which solver s found a provably optimal solution. Figure 6 shows a performance profile of the instances that were solved in two CPU hours by at least one of the solvers. The graph shows that bonsaiG and MINTO were able to solve the largest fraction of the instances the fastest. The solvers MINTO and CBC were able to find a provably optimal solution within the time limit for the largest largest fraction of instances, most likely because these two solvers contain the largest array of specialized MILP solution techniques.

For instances that were not solved to optimality by any of the six solvers in the study, we

Figure 6: Performance Profile of MILP Solver on Unsolved Instances

used the value of the best solution found as the quality measure. Under this measure, $\rho_s(1)$ is the fraction of instances for which solver s found the best solution among all the solvers, and $\rho_s(\infty)$ is the fraction of instances for which solver s found at least one feasible solution. In Figure 6, we give the performance profile of the six MILP solvers on the instances for which no solver was able to prove the optimality of the solution. SYMPHONY was able to obtain the largest percentage of good feasible solutions, and the performance of GLPK was also laudable in this regard. This conclusion is somewhat surprising since neither SYMPHONY nor GLPK contain a specialized primal heuristic designed for finding feasible solutions. This seems to indicate that the primal heuristics existing in these noncommercial codes are relatively ineffective. Implementation of a state-of-the-art primal heuristic in a noncommercial code would be a significant contribution.

7 Future Trends and Conclusions

In closing, we want to mention the work of two groups that have been strong supporters and developers of open code and are well-positioned to support such development for many years

into the future. The first is the COIN-OR Foundation, a non-profit foundation mentioned several times in this paper, part of whose mission it is to promote the development of open-source software for operations research [53]. This foundation, originally a loose consortium of researchers from industry and academia founded by IBM, has become a major provider of open-source optimization software and is poised to have a large impact on the field over the coming decade. The second is the NEOS (Network Enabled Optimization System) project [21, 23]. NEOS provides users with the ability to solve optimization problems on a remote server using any of a wide range of available solvers. At current count, 55 different solvers for a variety of different optimization problem types are available for use. Interfaces to the noncommercial MILP solvers CBC, GLPK, and MINTO are available on NEOS. To use NEOS, the user submits a problem represented in a specified input format (e.g., MPS, AMPL, GMPL, or LP) through either an e-mail interface, a web interface, or a specialized client program running on the user’s local machine. The instance is sent to the NEOS server, which locates resources to run the instance and sends the results back to the user. Because the job runs remotely, this provides the user with the ability to test multiple solvers without downloading and installing each of them individually. The NEOS project has been solving optimization problems on-line since 1991, and currently handles over 10,000 optimization instance each month.

As for the future, we see no slowing of the current trend toward the development of competitive noncommercial software for solving MILPs. A number of exciting new open-source projects are currently under development and poised to further expand the offerings to users of optimization software. Among these is the Abstract Library for Parallel Search (ALPS), a C++ class library for implementing parallel search algorithms planned that is the planned successor to BCP [88]. ALPS will further generalize many of the concepts present in BCP, providing the ability to implement branch-and-bound algorithms for which the bounding procedure is not necessarily LP-based. A second framework, called DECOMP, will provide the ability to automate the solution of decomposition-based bounding problems, that is, those based on Lagrangian relaxation or Dantzig-Wolfe decomposition [70]. Both of these frameworks will be available as part of the COIN-OR software suite. A new generation of the Open Solver Interface supporting a much wider range of problem types and with better model-building features is under development by COIN-OR, along with a new open standard based on LPFML for describing mathematical programming instances [32]. Finally, a MILP solver that integrates techniques from constraint programming with those described here is also under development and due out soon [1].

On the whole, we were impressed by the vast array of packages and auxiliary tools available, as well as the wide variety of features exhibited by these codes. The most significant features still missing in open codes are effective logical preprocessors and primal heuristics.

More effort is needed in developing tools to fill this gap. Although noncommercial codes will most likely continue to lag behind commercial codes in terms of raw speed in solving generic MILPs out of the box, they generally exhibit a much greater degree of flexibility and extensibility. This is especially true of the solver frameworks, which are designed specifically to allow the development of customized solvers. A number of features that appear in noncommercial codes, such as parallelism, the ability to support column generation, and the ability to solve multi-criteria MILPs, simply do not exist in most commercial codes. Although the noncommercial codes are in general slower than the best commercial codes, we believe that many users will be genuinely satisfied with the features and performance of the codes reviewed here and we look forward to future developments in this fast-growing area of software development.

Acknowledgment

The authors would like to thank Kjell Eikland, John Forrest, Matthew Galati, Lou Hafer, and Matthew Saltzman for their insightful comments that helped to improve the presentation.
